Abstract. The existence of two stationary solutions of the nonlinear Boltzmann equation for inelastic hard spheres or disks is investigated. They are restricted neither to weak dissipation nor to small gradients. The one-particle distribution functions are assumed to have a scaling property, namely that all the position dependence occurs through the density and the temperature. At the macroscopic level, the state corresponding to both is characterized by uniform pressure, no mass flow, and a linear temperature profile. Moreover, the state exhibits two peculiar features. First, there is a relationship between the inelasticity of collisions, the pressure, and the temperature gradient. Second, the heat flux can be expressed as being linear in the temperature gradient, i.e. a Fourier-like law is obeyed. One of the solutions is singular in the elastic limit. The theoretical predictions following from the other one are compared with molecular dynamics simulation results and a good agreement is obtained in the parameter region in which the Fourier state can be actually observed in the simulations, namely not too strong inelasticity.

Keywords: granular matter, kinetic theory of gases and liquids
1. Introduction

The knowledge of dilute granular gases has improved greatly in the last few years [1]–[3]. Among many others, one of the fundamental reasons for studying granular gases is that they are considered a proving ground for kinetic theory and non-equilibrium statistical mechanics. The underlying idea is that the grains can be likened to atoms or molecules and, therefore, granular gases can be likened to molecular gases. Due to the inherent energy dissipation in collisions between grains, there is no equilibrium state for granular gases and all of their states are of non-equilibrium nature. At a phenomenological level, granular gases exhibit many similarities with ordinary gases, although they also show some strong differences [4].

Grains are often modeled as inelastic hard spheres or disks and, in the simplest versions of models, tangential friction is neglected. For such models, the inelastic Boltzmann kinetic equation [5] provides an accurate starting point for studying low density granular gases. The validity of this equation is justified on exactly the same grounds as its elastic, molecular, limit. It can be derived either heuristically or from the Liouville equation in the asymptotic small density limit [6]. Moreover, the theoretical predictions derived from it have been found to be in very good agreement with molecular dynamics simulation results, when the comparison is carried out inside the appropriate range of the parameters defining the system. The above includes the velocity distribution of the simplest possible state of a granular gas, the so-called homogeneous cooling state [7], and its exponential tail [8, 9], the inelastic hydrodynamic equations to Navier–Stokes order, and the expressions for the transport coefficients appearing in them [10, 11]. More severe conditions such as the initial departure of a granular gas from homogeneity due to an instability have also been investigated [12], with the finding again that the Boltzmann equation can be used to accurately predict the behavior of the system in the low density limit.
The Chapman–Enskog procedure for deriving hydrodynamic equations assumes the existence of special kinds of solutions of the Boltzmann equation, the normal solutions, and that they can be constructed by means of an expansion in a formal inhomogeneity parameter \[13,14\]. The hydrodynamic Navier–Stokes equations correspond to keeping contributions to the distribution function up to the first order in the gradients, giving rise to terms in the hydrodynamic equations of second order in the gradients, when employed in the formal expressions for the heat and momentum fluxes. A peculiarity of granular gases is that hydrodynamic gradients are often induced by inelasticity. This holds particularly in the case of steady states, since the only way of compensating for the energy dissipation in collisions is through energy fluxes associated with gradients in the system. Consequently, in these systems there is a coupling between gradients and inelasticity, so the restriction to small gradients, as is the case for the Navier–Stokes equations, implies in many cases the restriction to small inelasticity too. For some states, like the steady shear flow, the situation is even more complex, since they are inherently rheological and the Navier–Stokes approximation never applies \[15\].

Of course, both limitations mentioned above, the assumption of a normal solution and that of an expansion in powers of the non-uniformity of the system, are overcome if the exact solution of the Boltzmann equation for a given state is known. In this case, all the transport properties can be computed with no assumption and/or approximation. The problem is that very little is known about exact inhomogeneous solutions of the Boltzmann equation that are relevant for transport. For molecular, elastic systems, the available exact solutions correspond to the very unrealistic case of Maxwell molecules \[16,17\]. On the other hand, a few years ago the existence of an inhomogeneous exact solution of the Boltzmann equation for smooth inelastic hard spheres or disks was suggested \[18\]. It has the property that all the spatial dependence in the velocity distribution occurs through its second velocity moment or, equivalently, the granular temperature. The macroscopic state is stationary and with gradients in only one direction. Moreover, the relationship between the heat flow and the temperature gradient can always be expressed in a linear form, regardless of the value of the parameters of the system. For this reason, it was referred to as the Fourier state.

Here the study of the Fourier state is undertaken in more detail. At the beginning, the aim of this study was twofold: to construct a solution of the equations derived in \[18\] beyond the Navier–Stokes approximation considered there, and to investigate to what extent the predicted state can be actually observed in molecular dynamics simulations. Nevertheless, the analysis to be presented indicates the possible existence of two different solutions of the inelastic Boltzmann equation having the properties associated with the Fourier state as described above. The first of them agrees, in the appropriate range of parameters, with the solution obtained in the Navier–Stokes approximation following from the Chapman–Enskog solution to the (inelastic) Boltzmann equation. On the other hand, the other solution cannot be inferred from a Chapman–Enskog-like algorithm. The reason is that it is singular, in the sense that its elastic limit does not correspond to any solution of the elastic Boltzmann equation. For similar reasons, this solution is not captured by the hydrodynamic Navier–Stokes equations for dilute granular gases either.

The remainder of the paper is organized as follows. The Fourier state of a dilute granular gas is defined in section 2, where the assumed form of the one-particle distribution function for this state is reviewed. Substitution of its expression into the inelastic...
Boltzmann equation and scaling of the velocity leads to a closed kinetic equation in which all the explicit space dependence has been eliminated. In section 3 a Sonine expansion of the distribution function solution of the Boltzmann equation is considered. The expansion is truncated to the lowest order that leads to nontrivial contributions to the even and odd parts of the distribution function. Equations for the coefficients of the remaining terms are obtained by taking velocity moments in the Boltzmann equation. In these equations only the lowest nonlinear contributions are kept. Then, two different solutions, referred to as ‘regular’ and ‘singular’, respectively, are identified. The origin and consistency of the singular solution are discussed in section 4. The purpose there is not to prove rigorously the existence of the solution, but to check the consistency of the calculations and approximations indicating that this is the case.

A comparison of the theoretical predictions with molecular dynamics simulation results is carried out in section 5. The state described by the singular solution of the Boltzmann equation has never been observed. A possible and probable reason for it is that this solution corresponds to a highly unstable state. On the other hand, for weak inelasticity, a good agreement is found for the bulk of the simulated systems with the predictions from the regular solution. As the inelasticity is increased, the Sonine approximation fails and later on, the Fourier state becomes very difficult to reach, in a significant space region of the system, in the simulations. Section 6 presents a brief discussion of the results, possible extensions, and also some open questions.

2. The Fourier state

Consider a dilute granular gas composed of smooth inelastic hard spheres \((d = 3)\) or disks \((d = 2)\) of diameter \(\sigma\) and mass \(m\), where \(\alpha\) is the velocity-independent coefficient of normal restitution. The one-particle distribution function \(f(r, v, t)\) is assumed to obey the inelastic Boltzmann equation [5]. For steady distributions depending on position only through the \(x\) coordinate, it has the form

\[
v_x \frac{\partial}{\partial x} f(x, v) = J[v|f],
\]

where the Boltzmann collision term \(J\) is a functional of the form

\[
J[v|f] \equiv \sigma^{-d-1} \int dv_1 \int d\hat{\sigma} \left( g \cdot \hat{\sigma} \right) g \cdot \hat{\sigma} \left[ \alpha^{-2} f(x, v') f(x, v_1') - f(x, v) f(x, v_1) \right].
\]

In the above expression, \(g \equiv v - v_1\) is the relative velocity, \(\hat{\sigma}\) is a unit vector along the line of centers of the two colliding particles at contact, \(\theta\) is the Heaviside step function, and \(v', v_1'\) are the precollisional velocities leading to \(v\) and \(v_1\). Moreover, attention here will be restricted to solutions having a vanishing average velocity, i.e.,

\[
\int dv \, v \, f(x, v) = 0.
\]

Balance equations are obtained in the usual way by taking velocity moments in equation (1),

\[
\frac{\partial}{\partial x} P_{x,i} = 0,
\]

\[
2(nd)^{-1} \frac{\partial q_x}{\partial x} + T(x) \zeta(x) = 0,
\]

doi:10.1088/1742-5468/2009/08/P08019
where \( n(x) \) and \( T(x) \) are the number density and the temperature, respectively,
\[
    n(x) \equiv \int d\mathbf{v} f(x, \mathbf{v}), \quad \frac{dn(x)T(x)}{2} \equiv \int d\mathbf{v} \frac{mv^2}{2} f(x, \mathbf{v}),
\]
and the pressure tensor \( P_{ij} \) and heat flux \( q \) are defined as
\[
    P_{ij} \equiv \int d\mathbf{v} mv_i v_j f(x, \mathbf{v}), \quad q \equiv \int d\mathbf{v} \frac{mv^2}{2} \mathbf{v} f(x, \mathbf{v}).
\]
Finally, \( \zeta(x) \) is the cooling rate due to the energy dissipation in collisions. Its expression is
\[
    \zeta(x) = \frac{m \pi (d-1)/2 \sigma^{d-1}(1-\alpha^2)}{4d \Gamma((d+3)/2) nT} \int d\mathbf{v} \int d\mathbf{v}_1 g^3 f(x, \mathbf{v}) f(x, \mathbf{v}_1).
\]
Equations (4) and (9) imply that the pressure tensor and, therefore, the pressure \( p = \sum_i P_{ii} / d = nT \) are uniform. Due to equations (4) and (6), the function \( \varphi \) must verify
\[
    \int dc \varphi(c) = 1, \quad \int dc c \varphi(c) = 0, \quad \int dc c^2 \varphi(c) = \frac{d}{2}.
\]
Using equation (9) in (5), taking into account equations (7) and (8), yields
\[
    \frac{dT}{dx} = p\sigma^{d-1} I[\varphi]
\]
with
\[
    I[\varphi] \equiv -\frac{(1-\alpha^2)\pi^{(d-1)/2}}{2\Gamma((d+3)/2)} \int dc \int dc_1 |c - c_1|^3 \varphi(c) \varphi(c_1)
    \int dc^2 c_x \varphi(c).
\]
It follows that the temperature profile is strictly linear in \( x \),
\[
    \frac{dT}{dx} = \theta = \text{constant}.
\]
Moreover, equation (11) establishes a relationship between the pressure, the temperature gradient, and the coefficient of restitution \( \alpha \) (through the function \( \varphi \)),
\[
    \frac{\theta}{p\sigma^{d-1}} = I[\varphi].
\]
The heat flux in the \( x \) direction is
\[
    q_x = \left[ \frac{2T(x)}{m} \right]^{1/2} p \int dc^2 c_x \varphi(c) = \left( \frac{2T}{m} \right)^{1/2} \int dc^2 c_x \varphi(c) \frac{dT}{dx}.
\]
This has the form of a Fourier law, with the heat flux coupled linearly to the temperature gradient. It is worth stressing that here it has been derived without any explicit restriction to small gradients. This is why this state was referred to as the Fourier state [18].

To get a closed equation for the function $\varphi$, equation (9) is substituted into the Boltzmann equation (1), taking into account equation (11). The result reads

$$-I[\varphi] \left\{ c_x \varphi(c) + \frac{c_x}{2} \frac{\partial}{\partial c} \cdot [c \varphi(c)] \right\} = \sigma^{1-d} J[c|\varphi].$$

From a mathematical point of view, the problem is fully analogous to the identification of the distribution function of the homogeneous cooling state [5].

3. Sonine expansion

Because of symmetry, the function $\varphi(c)$ must be an even function of the vector component of $c$ perpendicular to the $x$ axis, $c_\perp$. Then, $\varphi$ is expanded in series of Sonine polynomials as

$$\varphi(c) = \pi^{-d/2} e^{-c^2} \sum_{i=0}^{\infty} \sum_{j=0}^{\infty} \left[ a_{ij} S_{-1/2}^{(i)}(c_x^2) S_{(d-3)/2}^{(j)}(c_\perp^2) + b_{ij} c_x S_{1/2}^{(i)}(c_x^2) S_{(d-3)/2}^{(j)}(c_\perp^2) \right].$$

Equation (17) have been chosen so as to be able to guarantee that the $\varphi$ verify equations (10) exactly to all orders, since they are only related to the values of the first few coefficients. Using the relation (19), it is obtained that the necessary and sufficient conditions for this are

$$a_{00} = 1, \quad b_{00} = 0, \quad a_{10} + (d-1)a_{01} = 0.$$ 

In the following, the expansion given in equation (17) will be considered to the lowest nontrivial order, keeping only the terms proportional to $a_{01}$ (and $a_{10}$), $b_{01}$, and $b_{10}$, and neglecting the remaining terms. This corresponds to the so-called first Sonine approximation [14]. Explicitly, the approximation considered can be expressed as

$$\varphi(c) = \pi^{-d/2} e^{-c^2} \left[ 1 - a_{01} (c^2 - dc_x^2) + \left( \frac{d-1}{2} b_{01} + \frac{3}{2} b_{10} \right) c_x - b_{01} c_x c^2 - (b_{10} - b_{01}) c_x^3 \right].$$

$$\text{doi:10.1088/1742-5468/2009/08/P08019}$$
It is worth emphasizing that this approximation does not imply by itself the isotropy of the state. For instance, we have
\[ \int dc c_x^2 \varphi(c) = \frac{1}{2} + \frac{(d-1)a_{01}}{2}, \quad \int dc c_x^2 \varphi(c) = \frac{d-1}{2} (1-a_{01}), \] (23)
indicating that the diagonal elements of the pressure tensor are not the same if \( a_{01} \) does not vanish. Also, the dimensionless heat flux
\[ Q_x = \left[ \frac{m}{2T(x)} \right]^{1/2} \frac{q_x}{p} = \int dc c_x^2 \varphi(c) \] (24)
can be decomposed into the two components
\[ Q_{xx} \equiv \int dc c_x^3 \varphi(c) = -\frac{3b_{10}}{4}, \] (25)
\[ Q_{x\perp} \equiv \int dc c_x c_y^2 \varphi(c) = -\frac{(d-1)b_{01}}{4}. \] (26)
This implies anisotropy in the energy being carried in the \( x \) direction. To identify the coefficients \( a_{01}, b_{01}, \) and \( b_{10}, \) velocity moments are taken in equation (16), using the expansion of \( \varphi(c) \) in the first Sonine approximation. The equation contains terms that are nonlinear in \( \varphi(c) \), leading consequently to contributions that are nonlinear in the coefficients to be determined. Here the simplification is made of keeping only terms up to second degree in the coefficients \( a_{01}, b_{01}, \) and \( b_{10}, \) i.e. neglecting those terms proportional to \( a_{01}^n b_{01}^m b_{10}^n \) with \( n_1 + n_2 + n_3 \geq 3 \). A similar approximation to determine the coefficient characterizing the first Sonine approximation to the distribution function of the homogeneous cooling state \([5,7]\) was found to lead to a very good estimate, even for strong inelasticity \([2,20]\). In the present case, the accuracy of the approximation being used is just assumed for the sake of simplicity, without further justification.

Consider \( I[\varphi] \) defined in equation (12). A quadratic calculation as indicated above gives
\[ \int dc \int dc_1 |c - c_1|^3 \varphi(c) \varphi(c_1) = \frac{2^{3/2} \Gamma((d+3)/2)}{\Gamma(d/2)} [1 + g(b_{01}, b_{10})], \] (27)
\[ g(b_{01}, b_{10}) \equiv \frac{45b_{10}^2 + 18(d-1)b_{01}b_{10} + 3(d^2 - 1)b_{01}^2}{64(d+2)(d+4)} \] (28)
and then, using equations (24)–(26), it follows that
\[ I[\varphi] = \frac{(1 - \alpha^2) \pi^{(d-1)/2} 2^{5/2}}{\Gamma(d/2) [(d-1)b_{01} + 3b_{10}]} [1 + g(b_{01}, b_{10})]. \] (29)
Now, equation (16) is multiplied by \( c_x^2 \) and integrated over \( c \). After some algebra, it is obtained that
\[ (1 - \alpha)(d-1)(b_{01} - 3b_{10}) = -a_{01} \left( \frac{(d-1)(2d + 3 - 3\alpha)}{(d+2)} \right) [(d-1)b_{01} + 3b_{10}] . \] (30)
Upon obtaining this expression, equation (28) has been employed. Notice that an independent relationship between the coefficients cannot be derived by multiplying

doi:10.1088/1742-5468/2009/08/P08019
The dimensionless parameters $a_{01}$, $b_{10}$, and $b_{01}$ determining the distribution function of the ‘regular’ Fourier state in the first Sonine approximation considered in the text, as a function of the coefficient of normal restitution $\alpha$. The solid lines correspond to $d = 2$ and the dashed ones to $d = 3$.

In figure 1 the parameters $a_{01}$, $b_{01}$, and $b_{10}$ are plotted as a function of $\alpha$ for the regular solution. The results corresponding to both $d = 2$ and $d = 3$ are shown. The parameters defining the singular solution are given in figure 2. It is seen that $a_{01}$ does not vanish in either of the two solutions for $\alpha \neq 1$, then indicating the anisotropy of the pressure tensor, as discussed above. In the limit $\alpha \to 1$, there is a strong difference between the behaviors of the regular and the singular solutions. While in the former the three coefficients tend to vanish, in the latter they tend to finite, non-vanishing values. Moreover, for the regular solution, $a_{01}$ becomes very small and $b_{01} \approx b_{10}$, in the limit of small inelasticity ($\alpha$ close to 1). This is consistent with the results obtained to Navier–Stokes order by the Chapman–Enskog procedure in the first Sonine approximation, that leads to a distribution function verifying $a_{01} = 0$, $b_{01} = b_{10}$ [21]. When the inelasticity of the system increases, the values of $b_{01}$ and $b_{10}$ for the regular solution both grow very fast and the difference between them becomes significant. On the other hand, the behavior of the singular solution for $\alpha \to 1$ strongly differs from the Chapman–Enskog solution, since not only do the three coefficients tend to non-zero values, but also the limits of $b_{01}$ and $b_{10}$...
The Fourier state of dilute granular gases

Figure 2. The dimensionless parameters $a_{01}$, $b_{10}$, and $b_{01}$ determining the distribution function of the 'singular' Fourier state in the first Sonine approximation considered in the text, as a function of the coefficient of normal restitution $\alpha$. The solid lines correspond to $d = 2$ and the dashed ones to $d = 3$.

are definitely different, having even opposite sign. A direct consequence of this behavior is that, while the first solution tends to the elastic equilibrium Gaussian for $\alpha \rightarrow 1$, the other one does not. This is the reason for qualifying them as regular and singular solutions, respectively.

4. The singular solution

It has been mentioned above that a peculiarity of the singular solution of the Boltzmann equation for the Fourier state is that the coefficients $b_{01}$ and $b_{10}$ do not vanish in the elastic limit, tending to values with opposite signs in the elastic limit. A direct implication of this, following from equations (25) and (26), is that the two components of the heat flux, $Q_{xx}$ and $Q_{x\perp}$, also have opposite signs. That means that particles moving in one direction have on average larger values of $v_x^2$, while particles moving in the opposite direction have, also on average, larger values of $v_{\perp}^2$. Although one can be prompted to conclude that something fundamental is being violated by this solution, we have not been able to identify any argument leading us to discard it a priori. A trivial first test of the consistency of the singular solution is provided by the feature that the net heat flux must vanish in the elastic limit, since the dissipation and, therefore, the temperature gradient vanish in it. In figure 3 the dimensionless heat flux $Q_x$ corresponding to the singular solution is plotted as a function of the coefficient of normal restitution. It is seen to vanish when $\alpha \rightarrow 1$, for both $d = 2$ and $d = 3$, as it should.

In order to get additional information about whether the singular solution is an artifact of the Sonine approximation carried out in section 3, it seems worth investigating the asymptotic behavior of the solutions of the Boltzmann equation (16) in the limit $\alpha \rightarrow 1$. Assume that in this limit, the asymptotic behavior of the solutions of the equation

doi:10.1088/1742-5468/2009/08/P08019
The Fourier state of dilute granular gases

Figure 3. The dimensionless heat flux $Q_x$ for the singular solution of the inelastic Boltzmann equation for the Fourier state. The solid line corresponds to $d = 2$ and the dashed one to $d = 3$.

reads

$$\varphi(c) \sim \varphi^{(0)}(c) + \epsilon^q \varphi^{(1)}(c), \quad (31)$$

where $\epsilon \equiv (1 - \alpha^2)^{1/2}$, and the parameter $q > 0$ and the functions $\varphi^{(0)}(c)$ and $\varphi^{(1)}(c)$ are to be determined in the following by consistency. As a consequence,

$$Q_x \sim Q_x^{(0)} + \epsilon^q Q_x^{(1)}, \quad (32)$$

with

$$Q_x^{(0),(1)} = \int dc \, c^2 \varphi^{(0),(1)}(c). \quad (33)$$

Similarly,

$$\gamma[\varphi] \equiv \frac{\pi^{(d-1)/2}}{2 \Gamma((d + 3)/2)} \int dc \int dc_1 |c - c_1|^3 \varphi(c) \varphi(c_1) \sim \gamma^{(0)} + \epsilon^q \gamma^{(1)}, \quad (34)$$

$$\gamma^{(0)} = \frac{\pi^{(d-1)/2}}{2 \Gamma((d + 3)/2)} \int dc \int dc_1 |c - c_1|^3 \varphi^{(0)}(c) \varphi^{(0)}(c_1), \quad (35)$$

$$\gamma^{(1)} = \frac{\pi^{(d-1)/2}}{\Gamma((d + 3)/2)} \int dc \int dc_1 |c - c_1|^3 \varphi^{(0)}(c) \varphi^{(1)}(c_1). \quad (36)$$

The asymptotic behavior of the inelastic Boltzmann collision operator is easily identified as

$$J[c|g] \sim J^{(0)}[c|g] + \epsilon^2 J^{(2)}[c|g], \quad (37)$$

where $J^{(0)}$ is the elastic Boltzmann collision operator and the explicit form of $J^{(2)}[c|g]$ will not be needed in the following.
Putting $\epsilon = 0$ in equation (16) it is obtained that
\[
Q_x^{(0)} J^{(0)}[c|\varphi^{(0)}] = 0.
\] (38)

Therefore, either
\[
Q_x^{(0)} = 0
\] (39)
or
\[
J^{(0)}[c|\varphi^{(0)}] = 0.
\] (40)

Since equation (40) implies that $\varphi^{(0)}(c)$ is the Gaussian for which the dimensionless heat flux vanishes, it is concluded that equation (39) is always verified. When equation (40) is also fulfilled, the behavior corresponding to the regular solution, and to the Chapman–Enskog expansion, is recovered. The other possibility, namely $J^{(0)}[c|\varphi^{(0)}] \neq 0$ but still with $Q_x^{(0)} = 0$, is expected to lead to the singular solution. To investigate this issue further, the next order balance in the Boltzmann equation (16) is considered. It is given by
\[
\epsilon^2 c_x \gamma^{(0)} \left\{ \varphi^{(0)}(c) + \frac{1}{2} \frac{\partial}{\partial c} \cdot [c \varphi^{(0)}(c)] \right\} \simeq \epsilon q \sigma^{1-d} Q_x^{(1)} J^{(0)}[c|\varphi^{(0)}].
\] (41)

If $Q_x^{(1)} \neq 0$, balance of this equation requires that $q = 2$. Then multiplication of the equation by $c_x^2$ and integration over $c$ yields
\[
\gamma^{(0)} Q_{xx}^{(0)} = -2Q_x^{(1)} \sigma^{1-d} \int dc c_x^2 J^{(0)}[c|\varphi^{(0)}],
\] (42)

with
\[
Q_{xx}^{(0)} = \int dc c_x^3 \varphi^{(0)}(c).
\] (43)

Similarly, multiplication by $c_\perp^2$ and integration over $c$ gives
\[
\gamma^{(0)} Q_{x\perp}^{(0)} = -2Q_x^{(1)} \sigma^{1-d} \int dc c_\perp^2 J^{(0)}[c|\varphi^{(0)}],
\] (44)

where $Q_{x\perp}^{(0)} = Q_x^{(0)} - Q_{xx}^{(0)}$. Summation of equations (43) and (44), taking into account that the collision operator $J^{(0)}$ conserves the kinetic energy, leads to equation (39) providing a consistency test for the existence of the singular solution. Moreover, since the singular solution differs from the Gaussian, there is no reason to expect the right-hand sides of equations (42) and (44) to vanish. In summary, the asymptotic behavior of the solutions of the Boltzmann equation is qualitatively consistent with the existence of the ‘singular’ solution discussed above. Going to higher order terms trying to actually determine the asymptotic values of the moments of the singular solutions seems a formidable task.
5. Molecular dynamics simulation results

The Fourier state described in the previous sections is a ‘bulk state’, in the sense that it is expected to be shown by a dilute granular gas far away from the boundaries under the appropriate conditions, e.g. stationarity, no macroscopic mass flow, and gradients in only one direction [19, 22]. Establishing whether or not this scenario can be generated with enough accuracy in particle simulations with idealized boundary conditions is not at all trivial. In principle, it could be thought that the bulk state would be reached by increasing the size of the system, while suitably scaling its properties [23]. However, due to the coupling between the gradients, the pressure, and the inelasticity in the Fourier state, the identification of the right way of scaling the system turns out to be far from trivial. Although several different attempts have been made, trying to reach the Fourier state corresponding to the singular solution in the simulations, we did not succeed, possibly because it is highly unstable. This is an issue that deserves to be investigated, and it can be done by following the same method as in [20]. Consequently, attention will be restricted in the following to the regular solution, and all the references to theoretical predictions in the remainder of this section must be understood as dealing with that solution, although it is not established explicitly for the sake of brevity.

The macroscopic one-dimensional state that we are considering is known to exhibit a hydrodynamic instability, leading to the development of transverse inhomogeneities [24, 25]. In a two-dimensional system with periodic boundary conditions in the $y$ direction, the instability is controlled by the aspect ratio of the system $L_y/L_x$, where $L_x$ and $L_y$ are the dimensions of the system in the direction of the gradient and perpendicular to it, respectively. For given values of all the other parameters, the instability shows up when the aspect ratio exceeds a given critical value. Of course, it is possible that other instabilities occur in different regions of the space defined by the physical parameters of the system.

To investigate the validity of the theoretical predictions presented in the previous sections and their accessibility, molecular dynamics (MD) simulations of a system of inelastic hard disks ($d = 2$) have been performed. The simulations started with the particles uniformly distributed on a square lattice and with a Gaussian velocity distribution. Several ways of injecting energy through the walls were investigated, and it was concluded that the most efficient one for generating a bulk region in the system is the so-called thermal walls approach [26, 27]. In these walls, particles are absorbed at the surface and instantaneously re-emitted with a velocity determined by an equilibrium Maxwell–Boltzmann distribution, with a given wall temperature. The simulation data reported in the following have been obtained with two thermal walls located at $x = 0$ and $x = L_x$, respectively, and with periodic boundary conditions in the $y$ direction.

In all the cases to be reported, it was found that, after a transient period, the system reached a macroscopic steady state with gradients only in the $x$ direction and no flow field. Moreover, the steady state seems to be stable, in the sense that the same state was always reached for the same boundary conditions, independently of the specific initial conditions being used. The results presented below have been time averaged, once the system was in the steady state, and also over several independent trajectories. The temperature parameters of the thermal walls were fixed as follows. First, the temperature $T_0$ of the wall located at $x = 0$ was arbitrarily fixed. Then, the temperature of the wall at $x = L_x$ was
Figure 4. Steady dimensionless pressure, temperature, and density profiles for a system of hard disks with $\alpha = 0.99$. The temperature has been scaled with some arbitrary reference value, $T_R$, actually the initial temperature of the system. The symbols are simulation data, the dashed straight line in the pressure profile is a guide for the eye, and the dashed line in the temperature profile is a linear fit of the data in the interval $50\sigma \leq x \leq 700\sigma$. The simulation parameters are $N = 3 \times 10^3$, $L_x = 10^3\sigma$, $L_y/L_x = 0.2$.

determined by using the theoretical prediction for the temperature profile, equation (11). In this calculation, it was taken into account that the temperature of the thermal wall at $x = 0$ ($x = L_x$) is expected to correspond to the temperature of the gas extrapolated to $x = -\lambda(0)$ ($x = L_x + \lambda(L_x)$), where $\lambda(x)$ is the local mean free path.

Figure 4 shows the pressure, temperature, and density profiles measured in a system with $\alpha = 0.99$. In agreement with the theoretical predictions, it is observed that the pressure is uniform and the temperature profile linear, outside a boundary layer. In this case, the bulk of the system, arbitrarily identified as the region in which the temperature profile is linear, extends over most of it. A much more demanding and fundamental check of the theory is presented in figure 5. There, the marginal velocity distribution $\varphi_x(c_x)$
defined by
\[ \varphi_x(c_x) = \int dc_y \varphi(c) \quad (45) \]
is plotted for three different values of \(x\), namely for the layers centered at \(x = 275\sigma\), \(475\sigma\), and \(675\sigma\), respectively. The results for the other layers in the bulk are similar. Of course, in each layer the velocities have been scaled with the local temperature. It is seen that the overlap of the data is very good over a wide range of velocities, hence confirming the scaling of the distribution function in equation (9). Moreover, the difference from a
The Fourier state of dilute granular gases

Gaussian (dashed line) is significant, while the theoretical prediction derived (solid line) here provides a much more accurate description of the distribution in the thermal velocity region, roughly $|c_x| < 2$. To investigate the tails of the velocity distribution, the latter is also plotted on a logarithmic scale. As expected, the theoretical prediction derived here fails to correctly describe the tails, since it is based on the first Sonine approximation. On the other hand, the scaling seems to be verified within the statistical uncertainties.

Finally, in figure 6, the dimensionless heat flux defined in equation (24) is plotted as a function of the position of the layer considered. Although for this property the statistical error, defined as the standard deviation of the measured values, is rather large, a quite uniform value along the system is neatly observed. Moreover, this value is in good agreement with the theoretical prediction following from equations (25) and (26), with the coefficients determined by equations (30), (A.1), and (A.2).

Similar results have been obtained for other values of the coefficient of restitution in the interval $0.9 \leq \alpha < 1$, although the bulk region in which the Fourier state shows up becomes narrower as $\alpha$ decreases. In addition, the first Sonine approximation becomes less accurate. Nevertheless, there is strong evidence that the assumed Fourier state is present. To illustrate these comments, in figure 7, the temperature and heat flux profiles are plotted for a system with $\alpha = 0.9$. Now the bulk of the system, identified as the region in which the temperature profile is linear and the heat flux uniform, is restricted to an interval roughly between $250\sigma$ and $550\sigma$. The reduced distribution function $\varphi(c)$ for three different positions inside the bulk region is shown in figure 8. Significant discrepancies with the theoretical prediction in the first Sonine approximation are observed. On the other hand, there seems to be a clear indication that the scaling assumed in equation (9) holds in the bulk of the system. This scaling and the presence of gradients only in the direction
Figure 7. Steady dimensionless temperature and heat flux profiles in a system of hard disks with $\alpha = 0.9$. The temperature $T_R$ is the initial temperature of the system. The symbols are simulation data, the dashed line in the temperature profile is a linear fit of the data in the interval $250\sigma$–$550\sigma$, and the dashed line in the heat flux profile is the theoretical prediction obtained in this paper. The simulation parameters are $N = 3 \times 10^3$, $L_x = 10^3\sigma$, $L_y/L_x = 2$.

perpendicular to the walls directly leads to the Fourier state discussed in section 2. A different issue is how to solve the Boltzmann equation to obtain the explicit expression for the one-particle velocity distribution of the state. The first Sonine approximation developed here clearly fails to give an accurate description of the tails of the velocity distribution.

By construction, the Sonine approximation is expected to lead to much more accurate results for the low velocity moments than for the complete one-particle distribution function itself. Moreover these moments contain the most relevant physical information on the macroscopic properties of the system. A striking property of the Fourier state
investigated here is the relationship (14) between the temperature gradient, the pressure and the coefficient of restitution. Then, in figure 9, the MD simulation values obtained for the quantity \( I \equiv \theta/p\sigma \) in the bulk of the system have been plotted as a function of the restitution coefficient for the interval \( 0.9 \leq \alpha < 1 \). These simulation values are seen to be in very good agreement with the theoretical prediction given by equation (29), where the coefficients \( a_{01}, b_{01}, \) and \( b_{10} \) are given by the solution of the system of equations (30), (A.1) and (A.2) corresponding to the regular Fourier state. Also plotted in figure 9 is the quantity \( I \), as computed from the hydrodynamic Navier–Stokes equations derived from the Boltzmann equation by means of the Chapman–Enskog procedure in the first Sonine approximation [21,28]. These equations also admit a solution with the properties of the Fourier state [22]. The Navier–Stokes prediction is seen to be very close to the result derived here. In fact, the difference between the two predictions is smaller than the statistical uncertainties of the simulation data.

Of course, another physically relevant moment is the heat flux \( q_x \), or its dimensionless form \( Q_x \) defined in equation (24). This quantity is shown as a function of the restitution coefficient in figure 10. The observed qualitative behavior is easily understood, since it follows from figure 7 that the magnitude of the temperature gradient increases as \( \alpha \) decreases. Again, there is a quite good agreement between the MD simulation results and the expression found in this paper, i.e. equations (24)–(26) and \( b_{01} \) and \( b_{10} \) obtained as indicated above and discussed in section 3 for the regular solution. As in figure 9, the result obtained from the hydrodynamic Navier–Stokes equations, using the first Sonine approximation, for the Fourier state has also been included, and it differs very slightly from the solution derived here.

Figure 8. The scaled distribution function for the same system as in figure 5. The symbols correspond to MD simulation data at three different values of the coordinate \( x \), as indicated in the inset. The solid line is the theoretical prediction using the first Sonine approximation derived in the text, equation (22). The dashed line is the Gaussian, included as a reference.
6. Summary and discussion

Two nontrivial solutions of the Boltzmann equation for smooth inelastic hard spheres or disks have been investigated. They describe a stationary state with constant pressure, temperature gradient in one direction, and no macroscopic mass flow. Quite peculiarly, the temperature profile is strictly linear and the heat flux can be expressed as proportional to it, without nonlinear contributions. In other words, the macroscopic state does not present any kind of rheological hydrodynamic effects. For this reason the state was termed a Fourier state. Although no rigorous mathematical proof of the existence of the solutions is given, it has been shown that supposing they exist, a consistent expression for them can be found under well defined approximations. One of the solutions is singular in the sense that it does not reduce to any solution of the elastic Boltzmann equation when the limit of the coefficient of normal restitution going to unity is considered. This provides an example of a possible normal solution of the Boltzmann equation that is not captured by the Chapman–Enskog procedure used to solve it. On the other hand, the other solution, termed regular, tends to an equilibrium Gaussian in the elastic limit. It is worth stressing that although the two distribution functions are quite different, they lead to qualitatively similar macroscopic states.

The singular state was never observed in the molecular dynamics simulations that we carried out, while the theoretical predictions corresponding to the other solution are in good agreement with the simulation data, in the parameter region in which the Fourier state is accessible to the simulations, e.g. for not too strong inelasticity.

In this study, attention has been restricted to the first Sonine approximation, mainly for the sake of simplicity and also in order to derive results in an analytical form. From this starting point, two extensions are possible. The first one is to incorporate more terms in the Sonine expansion of the distribution function, solving the resulting equations numerically. A way of implementing this is by following the method developed in [29], that is tailored to solving the Boltzmann equation without considering any gradient expansion. The second extension refers to the tails of the distribution function. An asymptotic analysis of the inelastic Boltzmann equation for the Fourier state shows that for large values of the component of the velocity in the opposite direction to the increase of the temperature, the marginal velocity distribution exhibits an algebraic tail [18]. This feature can also be analyzed in a numerically exact way by using the method presented in [29]. This would allow us to, for instance, predict the amplitude of the algebraic decay.

Future work should also attempt to put the existence of the Fourier state solution(s) of the Boltzmann equation on a more rigorous mathematical footing. Even if only the regular solution exists and this happens in some well defined limit, it should be an important result, since it would provide an explicit nontrivial normal solution of the Boltzmann equation. Moreover, the Fourier state also offers the opportunity of studying hydrodynamic fluctuations and correlations in a far from equilibrium state, without resorting to expansions in the gradients of the fields.

Appendix. Two-moment equations for the Fourier state in the first Sonine approximation

Multiplication of equation (16) by $c^2$ and integration over $c$ leads to

$$
64d(d+2)(d+4)(1-\alpha)[1 + 2(d-1)a_{01}]
- (d-1)[13 + 51\alpha - 15d - 3\alpha d - 4d^2(1 + 3\alpha)]b_{01}^2
- 9[75 + 4d(21 + 4d - 9\alpha) - 139\alpha]b_{10}^2
- 6(d-1)[29 + 8d(5 + d - 3\alpha) - 93\alpha]b_{01}b_{10} = 0.
\tag{A.1}
$$

In a similar way, multiplication by $c^2x$ yields

$$
64d(d+2)(d+4)(1-\alpha)[d + 2 + (d + 1)(d + 4)a_{01}]
+ (d-1)[262 - 390\alpha - 7d + 231\alpha d - d^2(193 + 44d - 3(43 + 4d\alpha)]b_{01}^2
- 9[246 + 235d + 44d^2 - (22 + 3d)(17 + 4d\alpha)]b_{10}^2
- 6(d-1)[250 - 378\alpha + 237d + 44d^2 - 3d(47 + 4d\alpha)]b_{01}b_{10} = 0.
\tag{A.2}
$$

In the calculations leading to the above relations, equation (29) has been used and only terms up to second degree in $a_{01}$, $b_{01}$, and $b_{10}$ have been kept, as discussed in section 3. The circles plotted in figure 1 have been obtained by solving equations (30), (A.1), and (A.2) for $d = 2$.
