We experimentally study the propagation of circularly polarized light in the sub-diffusion regime by exploiting enhanced backscattering (EBS, also known as coherent backscattering) of light under low spatial coherence illumination. We demonstrate for the first time that circular polarization memory effect exists in EBS over a large range of scatterers’ sizes in this regime. We show that EBS measurements under low spatial coherence illumination from the helicity preserving and orthogonal helicity channels cross over as the mean free pathlength of light in media varies, and that the cross point indicates the transition from multiple to double scattering in EBS of light.

PACS numbers: 42.25.Dd, 42.25.Kb, 42.25.Ja.

The circular polarization memory effect is an unexpected preservation of the initial helicity (or handedness) of circular polarization of multiply scattered light in scattering media consisting of large particles. Mackintosh et al. [1] first observed that the randomization of the helicity required unexpectedly far more scattering events than did the randomization of its propagation in media of large scatterers. Bicout et al. [2] demonstrated that the memory effect can be shown by measuring the degree of circular polarization of transmitted light in slabs. Using numerical simulations of vector radiative transport equations, Kim and Moscoso [3] explained the effect as the result of successive near-forward scattering events in large scatterers. Recently, Xu and Alfano [4] derived a characteristic length of the helicity loss in the diffuse regime and showed that this characteristic length was greater than the transport mean free pathlength \( l_s^* \) for the scatterers of large sizes. Indeed, the propagation of circularly polarized light in random media has been investigated mainly using either numerical simulations or experiments in the diffusion regime, in part because its experimental investigation in the sub-diffusion regime has been extremely challenging. Therefore, the experimental investigation of circularly polarized light in the low-order scattering (or short traveling photons) regime using enhanced backscattering (EBS, also known as coherent backscattering) of light under low spatial coherence illumination will provide a better understanding of its mechanisms and the polarization properties of EBS as well.

EBS is a self-interference effect in elastic light scattering, which gives rise to an enhanced scattered intensity in the backward direction. In our previous publications, [5-8] we demonstrated that low spatial coherence illumination (the spatial coherence length of illumination \( L_{sc} \ll l_s^* \) ) dephases the time-reversed partial waves outside its finite coherence area, rejecting long traveling waves in weakly scattering media. EBS under low spatial coherence illumination (\( L_{sc} \ll l_s^* \)) is henceforth referred to as low-coherence EBS (LEBS). The angular profile of LEBS, \( I_{LEBS}(\theta) \), can be expressed as an integral transform of the radial probability distribution \( P(r) \) of the conjugated time-reversed light paths:[6-8]

\[
I_{LEBS}(\theta) \propto \int_0^\infty C(r) r P(r) \exp(i2\pi r \theta/\lambda) dr, \tag{1}
\]

where \( r \) is the radial distance from the first to the last points on a time-reversed light path and \( C(r) = |2J_1(r/L_{sc})/(r/L_{sc})| \) is the degree of spatial coherence of illumination with the first order Bessel function \( J_1 \). [9] As \( C(r) \) is a decay function of \( r \), it acts as a spatial filter, allowing only photons emerging within its coherence areas (\( \sim L_{sc}^2 \)) to contribute to \( P(r) \). Therefore, LEBS provides the information about \( P(r) \) for a small \( r (\ll 100 \mu m) \) that is on the order of \( L_{sc} \) as a tool for the investigation of light propagation in the sub-diffusion regime.

To investigate the helicity preservation of circularly
polarized light in the sub-diffusion regime by exploiting LEBS, we used the experimental setup described in detail elsewhere.[5,6] In brief, a beam of broadband cw light from a 100 W xenon lamp (Spectra-Physics Oriel) was collimated using a 4-f lens system, polarized, and delivered onto a sample with the illumination diameter of 3 mm. By changing the size of the aperture in the 4-f lens system, we varied spatial coherence length $L_{sc}$ of the incident light from 35 μm to 200 μm. The temporal coherence length of illumination was 0.7 μm with the central wavelength = 520 nm and its FWHM = 135 nm. The circular polarization of LEBS signals was analyzed by means of an achromatic quarter-wave plate (Karl Lambrecht) positioned between the beam splitter and the sample. The light backscattered by the sample was collected by a sequence of a lens, a linear analyzer (Lambda Research Optics), and a CCD camera (Princeton Instruments). We collected LEBS signals from two different circular polarization channels: the helicity preserving (h||h) channel and the orthogonal helicity (h.Lh) channel. In the (h||h) channel, the helicity of the detected circular polarization was the same as that of the incident circular polarization. In the (h.Lh) channel, the helicity of the detected circular polarization was orthogonal to that of the incident circular polarization.

In our experiments, we used media consisting of aqueous suspensions of polystyrene microspheres ($n_{sphere} = 1.599$ and $n_{water} = 1.335$ at 520 nm) (Duke Scientific) of various radii $a = 0.05, 0.10, 0.15, 0.25,$ and 0.45 μm (the size parameter $ka = 0.8 - 7.2$ and the anisotropic factor $g = 0.11 - 0.92$). The dimension of the samples was $π × 252 \text{mm}^2 × 50 \text{mm}$. Using Mie theory,[10] we calculated the optical properties of the samples such as the scattering mean free pathlength of light in the medium $l_s (= 1/μ_s$, where $μ_s$ is the scattering coefficient), the anisotropy factor $g (= \text{the average cosine of the phase function}$), and the transport mean free pathlength $l_s^* (= 1/μ_s^* = l_s/(1 - g)$, where $μ_s^*$ is the reduced scattering coefficient). We also varied $L_{sc}$ from 40 to 110 μm. We used $g$ as a metric of the tendency of light to be scattered in the forward direction.

The total experimental backscattered intensity $I_T$ can be expressed as $I_T = I_{SS} + I_{MS} + I_{EBS}$, where $I_{SS}$, $I_{MS}$, and $I_{EBS}$ are the contributions from single scattering, multiple scattering, and interference from the time-reserved waves (i.e., EBS), respectively. In media of relatively small particles (radius, $a ≤ \lambda$), the angular dependence of $I_T(θ)\text{ around the backward direction is primarily}$ due to the interference term, while the multiple and single scattering terms have weaker angular dependence. Thus, $I_{SS} + I_{MS} (= \text{the baseline intensity})$ can be measured at large backscattering angles ($θ > 3^\circ$). Conventionally, the enhancement factor $E = 1 + I_{EBS}(θ = 0^\circ)/(I_{SS} + I_{MS})$ is commonly used. However, in the studies of circularly polarized light, the enhancement factor should be modified, because the intensity of multiple scattering can be different in the two different channels and because in the (h||h) channel, single scattering is suppressed due to the helicity flip. Thus, in our studies, we calculated $I_{EBS}$ by subtracting $I_{SS} + I_{MS}$ from $I_T$.

Figure 1 shows representative LEBS intensity profiles $I_{LEBS}(θ)$ from the suspension of the microspheres with $a = 0.15$ μm ($ka = 2.4$ and $g = 0.73$ at $λ = 520$ nm). $I_{LEBS}$ and $I_{LEBS}^\perp$ denote from the (h||h) and (h.Lh) channels, respectively. We varied $l_s^*$ from 67 to 1056 μm ($l_s$ from 18 to 285 μm) with $L_{sc} = 110$ μm. In Fig. 2(a), we plot as a function of $l_s^*$ (the lines are third-degree polynomial fitting), showing two characteristic regimes: (i) the multiply scattering regime ($L_{sc} ≥ l_s^*$) and (ii) the minimally scattering regime ($L_{sc} ≤ l_s^*$). As expected, in the multiply scattering regime (i), $I_{LEBS}$ is higher than $I_{LEBS}^\perp$ because of the reciprocity principle in the (h||h) channel. On the other hand, in the minimal scattering regime (ii), a priori surprisingly, $I_{LEBS}^\perp$ is lower than $I_{LEBS}$. This is because in this regime, LEBS originates mainly from the time-reversed paths of the minimal number of scattering events in EBS (i.e., mainly double scattering) in a narrow elongated coherence volume.[8] In this case, the direction of light scattered by one of the scatterers should be close to the forward direction, while the direction of the light scattered by the other scatterer should be close to the backscattering that flips the helicity of circular polarization. After the cross point, the difference between and remains nearly constant, indicating that LEBS reaches to the asymptotic regime of double scattering.

More importantly, Fig. 2(a) shows that and $I_{LEBS}^\perp$ and $I_{LEBS}$ cross over at $l_s^* = 408$ μm ($l_s = 110$ μm). The cross point can be understood in the context of the circular polarization memory effect as follows. As shown in the inset of Fig. 2(b), at the cross point, $I_0 C(r)P(r) = I_0 C(r)P(∥)(r)$, where $P(∥)(r)$ and $P(⊥)(r)$ are the radial intensity distributions of the (h||h) and (h.Lh) channels, respectively. Thus, the cross point $R_0$ determines the optical properties ($l_s^*$ or $l_s$) such that $\int_0^{L_{sc}} P(∥)(r) = $...
In summary, we experimentally investigated for the first time the circular polarization memory effect in the sub-diffusion regime by taking advantage of LEBs, which suppresses time-reserved waves beyond the spatial coherence area; and thus isolates low-order scattering in weakly scattering media. We reported that LEBs introduces the new length scale (i.e., cross point) at which the degree of circular polarization becomes zero; and the scale is determined by both the spatial coherence length of illumination and the optical properties of the media. Using the cross point of the LEBs measurements from the \( (h||h) \) and \((h\perp h) \) channels, we further elucidated the memory effect in the sub-diffusion regime. Our results demonstrate that the memory effect exists in the EBS phenomenon. Furthermore, we show that the cross point is the transition point from multiple scattering to double scattering events this regime. Finally, our results will further facilitate the understanding of the propagation of circularly polarized light in weakly scattering media such as biological tissue.
