Abstract. We demonstrate that not only the production of virtual photons decaying into low-mass lepton pairs, but also the one of weak bosons at large transverse momenta is dominated by quark-gluon scattering. Measurements of these processes at the LHC can therefore provide useful constraints on the parton densities in the proton, in particular the one of the gluon, and their nuclear modifications.

1. Introduction

Parton distribution functions (PDFs) in protons and nuclei are traditionally determined in deep-inelastic electron scattering. While the (valence) quark densities can in this way well be determined, the gluon and sea quark densities enter only at higher order in perturbation theory, so that they are less well determined, in particular at very small and large momentum fractions $x$. Therefore, constraints from other hard scattering processes like inclusive hadron or jet production must be added in global analyses [1, 2, 3]. In nuclear collisions, the free proton PDFs are modified by the presence of the surrounding nucleons. From small to large $x$, shadowing, antishadowing and EMC effects, Fermi motion and isospin modifications occur. These effects are currently much less well determined than the PDFs in free protons and are parametrised by various groups [4, 5, 6, 7].

Prompt photon production at sufficiently large transverse momentum $p_T$ is known to be dominated by quark-gluon scattering, the so-called QCD Compton process, rather than quark-antiquark scattering. It can therefore in principle provide additional constraints on the gluon density and its nuclear modifications [8, 9]. However, fragmentation contributions lead to additional uncertainties [10, 11] and must be reduced by applying isolation criteria [12]. These difficulties do not occur with slightly virtual photons decaying into lepton pairs with small invariant mass, which are still dominantly produced in the QCD Compton process and can thus serve as a surrogate for prompt-photon production [13, 14]. As we have recently shown and will describe in this presentation, even $Z$ and $W$ boson production can serve to constrain the gluon PDFs in the proton at large $x$, if the transverse momentum of the produced vector boson is much larger than its mass [15], while nuclear modification effects can be constrained from low-mass lepton pair production in proton-ion collisions at the LHC [16].

2. Massive vector boson production at the LHC

The production of $W$ and $Z$ bosons at the LHC with a centre-of-mass energy of $\sqrt{s} = 7$ TeV has recently been measured by the ATLAS [17] and CMS [18] collaborations out to $p_T$ values of 600 GeV. The corresponding distribution for $Z$ bosons is shown in Fig. 1 (top). While at $p_T > 65$ GeV our perturbative calculation at next-to-leading order (NLO) is sufficient, this calculation diverges at low $p_T$ due to large logarithms and must be resummed, which we do up to next-to-leading logarithmic accuracy. As one can see, the theoretical predictions then agree very nicely with the data also at small $p_T$. Similar results have been obtained for the production of $W$ bosons [15].

Intuitively, one might expect massive $Z$ and $W$ bosons to be produced dominantly through the Drell-Yan process, i.e. in quark-antiquark annihilation, where a large fraction of longitudinal momentum is transferred from the proton to the parton. At the LHC, this is only true at small transverse momenta of the vector boson, as can be seen from Fig. 1 (bottom). When $p_T > M_{W,Z}$, the mass of the vector boson becomes less relevant, so that the QCD Compton process eventually takes over as it does for real and virtual photon production.

3. Parton densities in the proton

The values of $x$ probed by the current data sets, as estimated by $x_T = 2p_T/\sqrt{s}$ at central rapidities, extend only to small and intermediate values of 0.01 ... 0.15, where the quark and gluon densities are relatively well constrained.

In Fig. 2 (top) we show that this changes dramatically as higher values of $p_T$ and $x$ are reached. The PDF uncertainty as estimated by the CT10 error sets (yellow band) then easily exceeds the theoretical uncertainty from scale variations at NLO (red lines). In addition, other PDF parametrisations can fall outside the CT10 error band, indicating that the latter has been underestimated due to the theoretical ansatz at the starting scale or due to the selection of data sets entering the global analysis. Reaching higher values of $p_T$ of course requires higher luminosity, which will however soon become available at centre-of-mass energies of up to $\sqrt{s} = 14$ TeV. At this energy, the $x$-axes of our figures can simply be rescaled by a factor of two.

Alternatively, large values of $x$ can be reached in the forward or backward rapidity regions. As we show in Fig. 2 (bottom), the PDF uncertainties then exceed those of the scale variations already at currently accessible $p_T$ values and can easily reach 100%.

4. Nuclear modifications of parton densities

Nuclear modifications of parton densities can be determined in ratios of cross sections of proton-ion over proton-proton collisions. These offer the advantage that theoretical uncertainties from scale variations and free proton PDFs cancel out to a large extent in the numerator and denominator, as do most experimental systematic uncertainties.

In 2013, the LHC collided protons with lead ions at a centre-of-mass energy of $\sqrt{s} = 5.02$ TeV with beams circulating in both directions. Reference data were also taken in proton-proton collisions at the same energy. In Fig. 3 we show that the cross section ratios for low-mass muon pairs produced in the forward direction and detected, e.g., with the ALICE muon spectrometer, are very sensitive to nuclear modification effects. If the protons circulate towards the muon spectrometer, the PDFs in the lead ion are produced at relatively low values of $x$, i.e. in the shadowing region (Fig. 3, top). Only at relatively large values of $p_T > 70$ GeV the antishadowing region is reached, and the exact transition point depends strongly on the nuclear

PDF parametrisation. The uncertainty in the shadowing effect is ±10% at low $p_T$ according to EPS09 and reaches -20% in the nCTEQ prediction, demonstrating again the strong bias of the theoretical ansatz at the starting scale and of the selection of data sets in the global analysis.

When the lead ions circulate towards the muon spectrometer (Fig. 3, bottom), large $x$ values are probed. There, one has to take into account the isospin effect (green curve) and the EMC effect, which for EPS09 is predicted for $p_T > 40$ GeV and $x > 0.4$. In the other parametrisations the antishadowing region extends over almost the entire $p_T$ range shown. Similar studies can be performed with electron-positron pairs in the central detectors of ALICE, ATLAS and CMS. With the latter two general purpose experiments, also much higher values of $p_T$ may eventually be reached.

5. Conclusion

In conclusion, not only low-mass lepton pairs can serve as important probes of the gluon density in the proton, in particular at large $x$, but also the weak $W$ and $Z$ bosons can play this role despite their mass, provided that their transverse momenta are sufficiently large for the QCD Compton process to become dominant. With low-mass lepton pairs, nuclear modifications of parton densities can in principle be studied in all relevant regimes, provided that sufficient beam time is allocated to proton-ion runs at the LHC to reach luminosities at least in the pb range. Measuring ratios of cross sections then allows for large cancellations of theoretical and experimental uncertainties, leading to considerable improvements of our current knowledge of parton distributions in bound protons.

Acknowledgments

The author thanks the organisers of this conference for the kind invitation to this very stimulating workshop and M. Brandt, C. Klein-Bösing, F. König and J. Wessels for their collaboration.
