Simplicity via Provability for Universal Prefix-free Turing Machines

Universality is one of the most important ideas in computability theory. There are various criteria of simplicity for universal Turing machines. Probably the most popular one is to count the number of states/symbols. This criterion is more complex than it may appear at a first glance. In this note we review recent results in Algorithmic Information Theory and propose three new criteria of simplicity for universal prefix-free Turing machines. These criteria refer to the possibility of proving various natural properties of such a machine (its universality, for example) in a formal theory, PA or ZFC. In all cases some, but not all, machines are simple.

1 The smallest universal Turing machine

Roughly speaking, a universal Turing machine is a Turing machine capable of simulating any other Turing machine. In Turing’s words:

“It can be shown that a single special machine of that type can be made to do the work of all.
It could in fact be made to work as a model of any other machine. The special machine may be called the universal machine.”

The first universal Turing machine was constructed by Turing [26, 27]. Shannon [23] studied the problem of finding the smallest possible universal Turing machine and showed that two symbols were sufficient, if enough states can be used. He also proved that “it is possible to exchange symbols for states and vice versa (within certain limits) without much change in the product.” Notable universal Turing machines include the machines constructed by Minsky (7-state 4-symbol) [15], Rogozhin (4-state 6-symbol) [22], Neary–Woods (5-state 5-symbol) [17]. Herken’s book [11] celebrates the first 50 years of universality.

Weak forms of universality were proved by Watanabe (4-state 5-symbol) [28], Cook [9] for Wolfram’s 2-state 5-symbol machine [29], Neary–Woods [16], and Smith [24] for Wolfram’s 2-state 3-symbol machine.

2 Universal prefix-free Turing machines

A prefix-free Turing machine, shortly, machine, is a Turing machine whose domain is a prefix-free set. In what follows we will be concerned only with machines working on the binary alphabet \{0, 1\}. A universal machine \(U\) is a machine such that for every other machine \(C\) there exists a constant \(c\) (which depends upon \(U\) and \(C\)) such that for every program \(x\) there exists a program \(x'\) with \(|x'| \leq |x| + c\) such

\[1\] The critique by Pratt [20, 21], the response in [19] and the forthcoming paper by Margenstern [14] show the subtlety of the notion of universality.
that $U(x') = C(x)$. Universal machines can be effectively constructed. For example, given a computable enumeration of all machines $(C_i)$, the machine $U$ defined by $U(0' 1 x) = C_i(x)$ is universal. The domains of universal machines have interesting computational and coding properties, cf. [7, 6].

3 Peano arithmetic and Zermelo–Fraenkel set theory

By $\mathcal{L}_A$ we denote the first-order language of arithmetic whose non-logical symbols consist of the constant symbols 0 and 1, the binary relation symbol $<$ and two binary function symbols $+$ (addition) and $\cdot$ (multiplication). Peano arithmetic, PA, is the first-order theory [12] given by a set of 15 axioms defining discretely ordered rings, together with induction axioms for each formula $\varphi(x_1, \ldots, x_n)$ in $\mathcal{L}_A$:

$$\forall \varphi(\varphi(0, y) \land \forall x(\varphi(x, y) \rightarrow \varphi(x + 1, y)) \rightarrow \forall x(\varphi(x, y)).$$

By PA $\vdash \theta$ we mean “there is a proof in PA for $\theta$”.

PA is a first-order theory of arithmetic powerful enough to prove many important results in computability and complexity theories. For example, there are total computable functions for which PA cannot prove their totality, but PA can prove the totality of every primitive recursive function (and also of Ackermann total computable, non-primitive recursive function), see [12].

Zermelo–Fraenkel set theory with the axiom of choice, ZFC, is the standard one-sorted first-order theory of sets; it is considered the most common foundation of mathematics. In ZFC set membership is a primitive relation. By ZFC $\vdash \theta$ we mean “there is a proof in ZFC for $\theta$”.

Our metatheory is ZFC. We fix a (relative) interpretation of PA in ZFC according to which each formula of $\mathcal{L}_A$ has a translation into a formula of ZFC. By abuse of language we shall use the phrase “sentence of arithmetic” to mean a sentence (a formula with no free variables) of ZFC that is the translation of some formula of PA.

4 Rudiments of Algorithmic Information Theory

The set of bit strings is denoted by $\Sigma^*$. If $s$ is a bit string then $|s|$ denotes the length of $s$. All reals will be in the unit interval. A computably enumerable (shortly, c.e.) real number $\alpha$ is given by an increasing computable sequence of rationals converging to $\alpha$. Equivalently, a c.e. real $\alpha$ is the limit of an increasing primitive recursive sequence of rationals. We will blur the distinction between the real $\alpha$ and the infinite base-two expansion of $\alpha$, i.e. the infinite bit sequence $\alpha_0 \alpha_1 \alpha_2 \cdots$ $\in \{0, 1\}$ such that $\alpha = 0.\alpha_0 \alpha_1 \alpha_2 \cdots$ $\in \{0, 1\}$ such that $\alpha = 0.\alpha_0 \alpha_1 \alpha_2 \cdots$ $\in \{0, 1\}$.

One of the major problems in algorithmic information theory is to define and study (algorithmically) random reals. To this aim one can use the prefix-complexity or constructive measure theory; remarkably, the class of “random reals” obtained with different approaches remains the same.

In what follows we will adopt the complexity-theoretic approach. Fix a universal machine $U$. The prefix-complexity induced by $U$ is the function $H_U : \Sigma^* \rightarrow \mathbb{N}$ ($\mathbb{N}$ is the set of natural numbers) defined by the formula: $H_U(x) = \min\{|p| : U(p) = x\}$. One can prove that this complexity is optimal up to an additive constant in the class of all prefix-complexities $H_C : C$ is a machine).

A c.e. real $\alpha$ is Chaitin-random if there exists a constant $c$ such that for all $n \geq 1$, $H_U(\alpha(n)) \geq n - c$. The above definition is invariant with respect to $U$. Every Chaitin-random real is non-computable, but

---

2See more in [1]. The above universal machine, called prefix-universal because universality is obtained by adjunction, is quite particular. There are universal machines which are not prefix-universal.
the converse is not true. Chaitin-random reals abound: they have (constructive) Lebesgue measure one, cf. [1].

The standard example of c.e. Chaitin-random real is the halting probability of a universal machine $U$(Chaitin’s Omega number):

$$\Omega_U = \sum_{U(x) < \infty} 2^{-|x|}.$$  

Each Omega number encodes information about halting programs in the most compact way. For example, the answers to the following $2^{n+1} - 1$ questions “Does $U(x)$ halt?” for all programs $|x| \leq n$, is encoded in the first $n$ digits of $\Omega_U$—an exponential rate of compression. Is this important? For example, to solve the Riemann hypothesis one needs to calculate the first 7,780 bits of a natural Omega number [3].

The following result characterises the class of c.e. Chaitin-random reals:

**Theorem 1** [8, 5, 13] The set of c.e. Chaitin-random reals coincides with the set of all halting probabilities of all universal machines.

C.e. random reals have been intensively studied in recent years, with many results summarised in [1, 10, 18].

## 5 Universal machines simple for PA

We start with the simple question: Can PA certify the universality of a universal machine?

A universal machine $U$ is called simple for PA if PA ⊢ “$U$ is universal”, i.e. PA can prove that a universal $U$, given by its full description, is indeed universal. For illustration, the results in this section will include full proofs.

As one might expect, there exist universal machines simple for PA:

**Theorem 2** [4] One can effectively construct a universal machine which is simple for PA.

**Proof.** The set of all machines PA can prove to be prefix-free is c.e., so if $(C_i)_i$ is a computable enumeration of provably prefix-free machines, then the machine $U_0$ defined by $U_0(0^i1x) = C_i(x)$ has the property specified in the theorem: PA ⊢ “$U_0$ is universal”.

However, not all universal machines are simple:

**Theorem 3** [4] One can effectively construct a universal machine which is not simple for PA.

**Proof.** Let $(f_i)_i$ be a c.e. enumeration of all primitive recursive functions $f_i : \mathbb{N} \to \Sigma^*$ and $(C_i)_i$ a c.e. enumeration of all prefix-free machines. Fix a universal prefix-free machine $U$ and consider the computable function $g : \mathbb{N} \to \mathbb{N}$ defined by:

$$C_{g(i)}(x) = \begin{cases} U(x), & \text{if for some } j > 0, \#\{f_1(1), f_1(2), \ldots, f_1(j)\} > |x|, \\ \infty, & \text{otherwise.} \end{cases}$$

For every $i$, $C_{g(i)}$ is a prefix-free universal machine iff $f_i(N)$ is infinite (if $f_i(N)$ is finite, then so is $C_{g(i)}$). Since the set of all indices of primitive recursive functions with infinite range is not c.e. it follows that PA cannot prove that for some $i$, $C_{g(i)}$ is universal.

Both results above are true for plain universal machines too. The above proofs work for plain universal machines, but a simpler proof can be given for the negative result.

---

3$U(x) < \infty$ means “$U$ is defined on $x$”. 
6 Universal machines simple for ZFC

Assume that the binary expansion of $\Omega_U$ is $0.\omega_1 \omega_2 \ldots$. For each digit $\omega_i$ we can consider two arithmetic sentences in ZFC, “$\omega_i = 0$”, “$\omega_i = 1$”. How many sentences of the above type can ZFC prove?

**Theorem 4** [8] Assume that ZFC is arithmetically sound (that is, each sentence of arithmetic proved by ZFC is true). Then, for every universal machine $U$, ZFC can determine the value of only finitely many bits of the binary expansion of $\Omega_U$, and one can calculate a bound on the number of bits of $\Omega_U$ which ZFC can determine.

Actually, we can precisely describe the “moment” ZFC fails to prove any bit of $\Omega_U$:

**Theorem 5** [2] Assume that ZFC is arithmetically sound. Let $i \geq 1$ and consider the c.e. random real

$$\alpha = 0.\alpha_1 \ldots \alpha_{i-1} \alpha_i \alpha_{i+1} \ldots,$$

where $\alpha_1 = \ldots = \alpha_{i-1} = 1, \alpha_i = 0$.

Then, we can effectively construct a universal machine $U$ (depending upon ZFC and $\alpha$) such that $\text{PA}$ proves the universality of $U$, ZFC can determine at most $i$ initial bits of $\Omega_U$ and $\alpha = \Omega_U$.

In other words, the moment the first 0 appears (and this is always the case because $\alpha$ is random) ZFC cannot prove anything about the values of the remaining bits.

By taking $\alpha < 1/2$ we get Solovay’s most “opaque” universal machine.

**Theorem 6** [25] One can effectively construct a universal machine $U$ such that ZFC (if arithmetically sound) cannot determine any bit of $\Omega_U$.

We say that a universal machine is $n$–simple for ZFC if ZFC can prove at most $n$ digits of the binary expansion of $\Omega_U$. In view of Theorem 5 for every $n \geq 1$ there exists a universal machine which is $n$–simple for ZFC. By Theorem 6 there exists a universal machine which is not 1–simple for ZFC.

7 Universal machines PA–simple for randomness

We first express Chaitin randomness in PA. A c.e. real $\alpha$ is provably Chaitin-random if there exists a universal machine simple for PA and a constant $c$ such that $\text{PA} \vdash “\forall n (H_U(\alpha(n)) \geq n - c)\”$.

In this context it is natural to ask the question: Which universal machines $U$ “reveal” to PA that $\Omega_U$ is Chaitin-random?

**Theorem 7** [4] The halting probability of a universal machine simple for PA is provably Chaitin-random.

In fact, Theorem 1 can be proved in PA:

**Theorem 8** [4] The set of c.e. provably Chaitin-random reals coincides with the set of all halting probabilities of all universal machines simple for PA.

Based on Theorem 7 we define another (seemingly more general) notion of randomness in PA. A c.e. real is provably-random (in PA) if there is a universal machine simple for PA and $\text{PA} \vdash “\Omega_U = \alpha\”$.

---

4This means that ZFC can prove only finitely many sentences of the form “$\omega_i = 0$”, “$\omega_i = 1$” and one can calculate a natural $N$ such that no sentence of the above type with $i \geq N$ can be proved in ZFC.

5Theorem 6 was obtained before Theorem 5.
Theorem 9 \cite{calude_hay_2008} A c.e. real is provably-random iff it is provably Chaitin-random.

In contrast with the case of finite random strings where ZFC (hence PA) cannot prove the randomness of more than finitely many strings, for c.e. reals we have:

Theorem 10 \cite{calude_hay_2008} Every c.e. random real is provably-random.

We say that a universal machine $U$ is PA–simple for randomness if $\text{PA} \vdash \text{"$\Omega_U$ is random."}$ In view of the Theorem 10 we get:

**Corollary 11** For every c.e. random real $\alpha$ there exists a PA–simple for randomness universal machine $U_0$ such that $\alpha = \Omega_{U_0}$.

However,

**Theorem 12** There exists a universal machine which is not PA–simple for randomness.

8 Conclusions

We have used some recent results in Algorithmic Information Theory to introduce three new criteria of simplicity for universal machines based on their “openness” in revealing information to a formal system, PA or ZFC. The type of encoding is essential for these criteria. This point of view might be useful in other contexts, specifically in automatic theorem proving. It would be interesting to “actually construct” the universal machines discussed in this paper.
