Games on recursive game graphs can be used to reason about the control flow of sequential programs with recursion. In games over recursive game graphs, the most natural notion of strategy is the modular strategy, i.e., a strategy that is local to a module and is oblivious to previous module invocations, and thus does not depend on the context of invocation. In this work, we study for the first time modular strategies with respect to winning conditions that can be expressed by a pushdown automaton. We show that such games are undecidable in general, and become decidable for visibly pushdown automata specifications. Our solution relies on a reduction to modular games with finite-state automata winning conditions, which are known in the literature. We carefully characterize the computational complexity of the considered decision problem. In particular, we show that modular games with a universal Büchi or co-Büchi visibly pushdown winning condition are \( \text{E} \times \text{PTIME} \)-complete, and when the winning condition is given by a \text{CARET} or \text{NWTL} temporal logic formula the problem is \( 2\text{E} \times \text{PTIME} \)-complete, and it remains \( 2\text{E} \times \text{PTIME} \)-hard even for simple fragments of these logics. As a further contribution, we present a different solution for modular games with finite-state automata winning condition that runs faster than known solutions for large specifications and many exits.

1 Introduction

Recursive state machines (RSMs) carefully model the control flow of systems with potentially recursive procedure calls [2]. A recursive state machine is composed of a set of modules, whose vertices can be standard vertices or can correspond to invocations of other modules. A large number of hardware and software systems fits into this class, such as procedural and object-oriented programs, distributed systems, communication protocols and web services.

In the open systems setting, i.e., systems where an execution depends on the interaction of the system with the environment, the natural counterpart of recursive state machines is two-player recursive game graphs. A recursive game graph (RGG) is essentially a recursive state machine where vertices are split into two sets each controlled by one of the players, and thus corresponds to pushdown games with an emphasis on the modules composing the system.

In this paper we focus on solving pushdown games on RGG in which the first player is restricted to modular strategies [7]. A strategy is a mapping that specifies, for each play ending into a controlled state, the next move. Modular strategies are formed of a set of strategies, one for each RGG module, that are local to a module and oblivious of the history of previous module activations, i.e., the next move in such strategies is determined by looking only at the local memory of the current module activation (by making the local memory persistent across module activations, deciding these games becomes undecidable already with reachability specifications [7]).

\*This work was partially funded by the MIUR grants FAR 2011-2012-2013, Università degli Studi di Salerno (Italy).
The main motivation for considering modular strategies is related to the synthesis of controllers [18, 20]: given a description of the system where some of the choices depend upon the input and some represent uncontrollable internal non-determinism, the goal is to design a controller that supplies inputs to the system such that it satisfies the correctness specification. Synthesizing a controller thus corresponds to computing winning strategies in two-player games, and a modular strategy would correspond to a modular controller.

The notion of modular strategy is also of independent interest and has recently found application in other contexts, such as, the automatic transformation of programs for ensuring security policies in privilege-aware operating systems [11], and a general formulation of the synthesis problem from libraries of open components [10].

The problem of deciding the existence of a modular strategy in a recursive game graph has been already studied with respect to \( \omega \)-regular specifications. The problem is known to be NP-complete for reachability specifications [7], \( \text{EXPTIME} \)-complete for specifications given as deterministic and universal Büchi or Co-Büchi automata, and \( 2\text{EXPTIME} \)-complete for LTL specifications [5].

In this paper, we study this problem with respect to several classes of specifications that can be expressed as a pushdown automaton. We show that in the general case the problem is undecidable. We thus focus on visibly pushdown automata (VPA) [8] specifications with Büchi or co-Büchi acceptance. In the following, we refer to this problem as the MVPG problem and omit the acceptance condition of the VPA by meaning either one of them.

Our main contributions are:

- We show a polynomial time reduction from the MVPG problem with deterministic or universal VPA specifications to recursive modular games over \( \omega \)-regular specifications. By [5], we get that this problem is \( \text{EXPTIME} \)-complete. We then use this result to show the membership to \( 2\text{EXPTIME} \) for the MVPG problem with nondeterministic VPA specifications.

- We show that when the winning condition is expressed as a formula of the temporal logics CARET [3] and NWTL [1] the MVPG problem is \( 2\text{EXPTIME} \)-complete, and hardness can be shown also for very simple fragments of the logics. In particular, we show a \( 2\text{EXPTIME} \) lower bound for the fragment containing only conjunctions of disjunctions of bounded-size path formulas (i.e., formulas expressing either the requirement that a given finite sequence is a subsequence of a word or its negation), that is in contrast with the situation in finite game graphs where \( \text{PSPACE} \)-completeness holds for larger significant fragments (see [4, 6]). On the positive side, we are able to show an exponential-time algorithm to decide the MVPG problem for specifications given as conjunctions of temporal logic formulas that can be translated into a polynomial-size VPA (such formulas include the path formulas).

- We also give a different solution for recursive games with finite-state automata specifications. Our approach yields an upper bound of \(|G|2^{O(d^2(k + \log d) + \beta)}\) for the MVPG problem, where \(d\) is the number of \(P\) (the VPA) states, \(k\) is the number of \(G\) (the RGG) exits, and \(\beta\) is the number of call edges of \(G\), i.e., the number of module pairs \((m, m')\) such that there is a call from \(m\) to \(m'\). The known solution [5] yields an \(|G|2^{O(kd^2 \log (kd))}\) upper bound. Thus, our solution is faster when \(k\) and \(d\) are large, and matches the known \(\text{EXPTIME} \) lower bound [5]. In addition we use one-way nondeterministic/universal tree automata instead of two-way alternating tree automata, thus we explicitly handle aspects that are hidden in the construction from [5].

**Related work.** Besides the already mentioned work that has dealt with modular games, but only for \( \omega \)-regular specifications [5] or reachability [7], other research on pushdown games have focused on the
standard notion of winning strategy. We recall that determining the existence of a standard winning strategy (i.e., non-modular) in pushdown games with reachability specifications is known to be EXPTIME-complete \[21\]. Deciding such games is 2EXPTIME-complete for nondeterministic visibly pushdown specifications and 3EXPTIME-complete for LTL and CARET specifications \[13\].

The synthesis from recursive-component libraries defines a pushdown game which is orthogonal to the MVPG problem: there the modules are already synthesized and the game is on the function calls. Deciding such games for NWTL is 2EXPTIME-complete \[15\]. The synthesis from open recursive-component libraries combines both this synthesis problem and the MVPG synthesis. Deciding the related game problem with reachability specifications is EXPTIME-complete \[10\]. Other synthesis problems dealing with compositions of component libraries are \[14, 9\], and for modules expressed as terms of the \(\lambda Y\)-calculus, \[19\].

2 Preliminaries

Given two positive integers \(i\) and \(j\), \(i \leq j\), we denote with \([i, j]\) the set of integers \(k\) with \(i \leq k \leq j\), and with \([j]\) the set \([1, j]\).

We fix a set of atomic propositions \(AP\) and a finite alphabet \(\Sigma\). A \(\omega\)-word over \(\Sigma\) is a mapping that assigns to each position \(i \in \mathbb{N}\) a symbol \(\sigma_i \in \Sigma\), and is denoted as \(\{\sigma_i\}_{i \in \mathbb{N}}\) or equivalently \(\sigma_1 \sigma_2 \ldots\).

**Recursive game graph.** A recursive game graph (RGG) is composed of game modules that are essentially two-player graphs (i.e., graphs whose vertices are partitioned into two sets depending on the player who controls the outgoing moves) with entry and exit nodes and two different kind of vertices: the nodes and the boxes. A node is a standard graph vertex and a box corresponds to invocations of other game modules in a potentially recursive manner (in particular, entering into a box corresponds to a module call and exiting from a box corresponds to a return from a module).

As an example consider the RGG in Fig. 1 where the vertices of player 0 (\(pl_0\)) are denoted with rounds, those of player 1 (\(pl_1\)) with squares and the rectangles denote the vertices where there are no moves that can be taken by any of the players and correspond to calls and exits. Atomic propositions \(p_a\), \(p_b\), \(p_c\), and \(p_d\) label the vertices. Each RGG has a distinct game module which is called the main module (module \(M_{in}\) in the figure). In analogy to many programming languages, we require that the main module cannot be invoked by any other module. A typical play starts in vertex \(e_{in}\). From this node, there is only one possible move to take and thus the play continues at the call to \(M_1\) on box \(b\), which then takes the play to the entry \(e_1\) in \(M_1\).

This is a vertex of the adversary, who gets to pick the transition and thus can decide to visit either \(u_3\) (generating \(p_a\)) or \(u_4\) (generating \(p_b\)). In any of the cases, the play will evolve reaching the exit and then the control will return to module \(M_1\) at the return vertex on box \(b\). Here \(pl_0\) gets to choose if generating \(p_c\) or \(p_d\) and so on back to the call to \(M_1\). Essentially, along any play alternatively \(pl_1\) chooses one between \(p_a\) and \(p_b\), and \(pl_0\) chooses one between \(p_c\) and \(p_d\). Formally, we have the following definitions.

**Definition 1. (Recursive Game Graph)** A recursive game graph \(G\) over \(AP\) is a triple \((M, m_{in}, \{S_m\}_{m \in M})\) where \(M\) is a finite set of module names, \(m_{in} \in M\) denotes the main module and for each \(m \in M\), \(S_m\) is a game module. A game module \(S_m\) is \((N_m, B_m, Y_m, E_{in}, E_{out}, \delta_m, \eta_m, \rho_m^0, \rho_m^1)\) where:

- \(N_m\) is a finite set of nodes and \(B_m\) is a finite set of boxes;
- \(Y_m : B_m \rightarrow (M \setminus \{m_{in}\})\) maps every box to a module;

\[\text{Figure 1: A sample RGG.}\]
En_m \subseteq N_m \text{ is a non-empty set of entry nodes; }

• Ex_m \subseteq N_m \text{ is a (possibly empty) set of exit nodes; }

• \delta_m : N_m \cup \text{Retns}_m \rightarrow 2^{N_m \cup \text{Calls}_m} \text{ is a transition function where } \text{Calls}_m = \{(b, e) | b \in B_m, e \in En_m(b)\} \text{ is the set of calls and } \text{Retns}_m = \{(b, e) | b \in B_m, e \in Ex_m(b)\} \text{ is the set of returns; }

• \eta_m : V_m \rightarrow 2^{AP} \text{ labels in } 2^{AP} \text{ each vertex from } V_m = N_m \cup \text{Calls}_m \cup \text{Retns}_m; \eta_m \text{ is such that }\eta_m(v) = \eta_m(v) \text{ where } v \in V_m. 

In the rest of the paper, we denote with: \(G\) an RGG as in the above definition; \(V = \bigcup_m V_m\) (set of vertices); \(B = \bigcup_m B_m\) (set of boxes); \(\text{Calls} = \bigcup_m \text{Calls}_m\) (set of calls); \(\text{Retns} = \bigcup_m \text{Retns}_m\) (set of returns); \(\text{Ex} = \bigcup_m \text{Ex}_m\) (set of exits); \(P^\ell = \bigcup_m P^\ell_m\) for \(\ell \in [0, 1]\) (set of all positions of \(pl_\ell\)) and \(\eta : V \rightarrow 2^{AP}\) such that \(\eta(v) = \eta_m(v)\) where \(v \in V_m\).

To ease the presentation we make the following assumptions (with \(m \in M\)):

• there is only one entry point to every module \(S_m\) and we refer to it as \(e_m\);

• there are no transitions to an entry, i.e., \(e_m \not\in \delta_m(u)\) for every \(u\);

• there are no transitions from an exit, i.e., \(\delta_m(x)\) is empty for every \(x \in \text{Ex}_m\);

• a module is not called immediately after a return from another module, i.e., \(\delta_m(v) \subseteq N_m\) for every \(v \in \text{Retns}_m\).

A (global) state of an RGG is composed of a call stack and a vertex, that is, each state of \(G\) is of the form \((\alpha, u) \in B^* \times V\) where \(\alpha = b_1 \ldots b_h, b_1 \in B_{m_0}, b_{i+1} \in B_{Y(b_i)}\) for \(i \in [h - 1]\) and \(u \in V_{Y(b_h)}\).

A play of \(G\) is a (possibly finite) sequence of states \(s_0 s_1 s_2 \ldots\) such that \(s_0 = (\varepsilon, e_m)\) and for \(i \in \mathbb{N}\), denoting \(s_i = (\alpha_i, u_i)\), one of the following holds:

– Internal move: \(u_i \in (N_m \cup \text{Retns}_m) \setminus \text{Ex}_m, u_{i+1} \in \delta_m(u_i)\) and \(\alpha_i = \alpha_{i+1};\)

– Call to a module: \(u_i \in \text{Calls}_m, \alpha_i = (b, e_m), u_{i+1} = e_m\) and \(\alpha_{i+1} = \alpha_i b;\)

– Return from a call: \(u_i \in \text{Ex}_m, \alpha_i = \alpha_{i+1} b, \) and \(u_{i+1} = (b, u_i)\).

Fix an infinite play \(\pi = s_0 s_1 \ldots\) of \(G\) where \(s_i = (\alpha_i, u_i)\) for each \(i \in \mathbb{N}\). With \(\pi \_g\) we denote \(s_0 \ldots s_k\) i.e., the prefix of \(\pi\) up to \(s_k\). For a finite play \(\pi\_s\) with \(\text{ctr}(\pi\_s)\) we denote the module \(m\) where the control is at \(s\), i.e., such that \(u \in V_m\) where \(s = (\alpha, u)\). We define \(\mu_\pi\) such that \(\mu_\pi(i, j)\) holds iff for some \(m \in M, u_i \in \text{Calls}_m\) and \(j\) is the smallest index s.t. \(i < j, u_j \in \text{Retns}_m\) and \(\alpha_i = \alpha_j (\mu_\pi\) captures the matching pairs of calls and returns in \(\pi\).

Modular strategies. Fix \(\ell \in [0, 1]\). A strategy of \(pl_\ell\) is a function \(f\) that associates a legal move to every play ending in a node controlled by \(pl_\ell\).

A modular strategy constrains the notion of strategy by allowing only to define the legal moves depending on the “local memory” of a module activation (every time a module is re-entered the local memory is reset).

Formally, a modular strategy \(f\) of \(pl_\ell\) is a set of functions \(\{f_m\}_{m \in M}\), one for each module \(m \in M\), where \(f_m : V_m^* P^\ell_m \rightarrow V_m\) is such that \(f_m(\pi, u) \in \delta_m(u)\) for every \(\pi \in V_m, u \in P^\ell_m\).

The local successor of a position in \(\pi\) is: the successor according to the matching relation \(\mu_\pi\) at matched calls, undefined at an exit or an unmatched call, and the next position otherwise. Formally, the local successor of \(j\), denoted \(\text{succ}_\pi(j)\), is: \(h\) if \(\mu_\pi(j, h)\) holds; otherwise, is undefined if either \(u_j \in \text{Ex}\) or \(u_j \in \text{Calls}\) and \(\mu_\pi(j, h)\) does not hold for every \(h > j\); and \(j + 1\) in all the remaining cases.
For each $i \leq |\pi|$, the local memory of $\pi_i$, denoted $\lambda(\pi_i)$, is the maximal sequence $u_{h_i}, \ldots, u_{j_i}$ such that $u_{h_i} = u_i$ and $j_{h+1} = \text{succ}_\pi(j_h)$ for each $h \in [k - 1]$. (Note that since the sequence is maximal, $u_{j_i} = e_m$ where $m = \text{ctr}(\pi_i)$.)

A play $\pi$ conforms to a modular strategy $f = \{f_m\}_{m \in M}$ if for every $i < |\pi|$, denoting $\text{ctr}(\pi_i) = m$, $u_i, u_j \in P_m$ implies that $u_{i+1} = f_m(\lambda(\pi_i))$.

Consider again the example from Fig. 1. A strategy of $P_1$ would only allow either one of the behaviors: “$P_1$ always picks $p_a$” or “$P_1$ always picks $p_b$.”

**Winning conditions and modular games.** A modular game on RGG is a pair $\langle G, L \rangle$ where $G$ is an RGG and $L$ is a winning condition. A winning condition is a set $L$ of $\omega$ words over a finite alphabet $\Sigma = 2^{\mathcal{AP}}$, where $\mathcal{AP}$ is a set of propositions. Given an RGG $G$, for a play $\pi = s_0s_1 \ldots$ of $G$, with $s_i = (q_i, u_i)$, we define the word $w_\pi = \eta(u_0)\eta(u_1) \ldots$, which is the mapping that assigns to each position the correspondent symbol from $\Sigma$. A modular strategy $f$ is winning if $w_\pi \in L$ for every play $\pi$ of $G$ that conforms to $f$. The modular game problem asks to determine the existence of a winning (modular) strategy of $pl_0$ in a given modular game. In the following sections, we consider $L$ given by pushdown, visibly pushdown automata and by LTL, CRET or NWTL formulas.

### 3 Pushdown specification

**Pushdown modular games.** A pushdown modular game is a pair $\langle G, \mathcal{P} \rangle$ where $G$ is an RGG and $\mathcal{P}$ is a pushdown automaton, whose accepted language defines the winning condition in $G$. A pushdown automaton $\mathcal{P}$ is a tuple $(Q, q_0, \Sigma, \Gamma, \delta, \gamma^\perp, F)$ where $Q$ is a finite set of states, $q_0 \in Q$ is the initial state, $\Sigma$ is a finite alphabet, $\Gamma$ is a finite stack alphabet, $\gamma^\perp$ is the bottom-of-stack symbol, $F \subseteq Q$ defines an acceptance condition, and $\delta : Q \times (\Sigma \cup \varepsilon) \times \Gamma \rightarrow 2^{Q \times \Gamma^*}$ is the transition function. A pushdown automaton is deterministic if it satisfies the following two conditions: - $\delta(q, \alpha, \gamma)$ has at most one element for any $q \in Q$, $\gamma \in \Gamma$ and $\alpha \in \Sigma$ (or $\alpha = \varepsilon$); - if $\delta(q, \varepsilon, \gamma) \neq \emptyset$ for any $q \in Q$ and $\gamma \in \Gamma$ then $\delta(q, \alpha, \gamma) = \emptyset$ for any $\alpha \in \Sigma$.

**Undecidability of pushdown specification.** The modular game problem becomes undecidable if we consider winning conditions expressed as standard (deterministic) pushdown automata. This is mainly due to the fact that the stack in the specification pushdown automaton is not synchronized with the call-return structure of the recursive game graph.

We prove the undecidability of our problem with pushdown specification by presenting a reduction from the problem of checking the emptiness of the intersection of two deterministic context-free languages.

Consider two context-free languages $L_1$ and $L_2$ on an alphabet $\Sigma = \{\sigma_1, \sigma_2, \ldots, \sigma_d\}$, which are accepted by two pushdown automata, $\mathcal{P}_1$ and $\mathcal{P}_2$, respectively. We want to construct an instance $\langle G, \mathcal{P} \rangle$ of a deterministic pushdown modular game problem such that exists a winning modular strategy for $pl_0$ in $\langle G, \mathcal{P} \rangle$ if and only if the intersection of $L_1$ and $L_2$ is not empty.

The basic idea of the reduction is to construct a game where $pl_1$ challenges $pl_0$ to generate a word from either $L_1$ or $L_2$, and $pl_0$ must match the choice of $pl_1$ without knowing it in order to win. We construct an RGG $G$ with two modules, $m_{\text{in}}$ and $m$ (see the Fig. 2).
The module \( m_{in} \) is the main module and is composed of an entry \( e_{in} \), two internal nodes \( u_1 \) and \( u_2 \), and one box \( b \) labeled with \( m \). The entry \( e_{in} \) belongs to \( pl_1 \) and has two transitions, one to each internal node. From \( u_1 \) and \( u_2 \) there is only one possible move, which leads to \( b \). The labeling function associates the symbol \( a_1 \) to \( u_1 \) and the symbol \( a_2 \) to \( u_2 \) with \( a_1,a_2 \not\in \Sigma \). The node \( e_{in} \) and the call \( (b,e_m) \) are both labeled with \( \# \not\in \Sigma \cup \{a_1,a_2\} \). Observe that since the only choice of \( pl_1 \) at \( e_{in} \), for any strategy \( f \) of \( pl_0 \) there are only two plays conforming to it: one going through \( u_1 \) and the other through \( u_2 \).

The module \( m \) is essentially a deterministic generator of any word in \( \{\#\}^* \Sigma^* \{\#\} \). The module \( m \) has one entry \( e_m \), \( |\Sigma| \) internal nodes \( v_1,v_2,\ldots,v_n \) and a sink node \( s \) (i.e., a node with only ingoing edges). All the vertices of \( m \) belong to \( pl_0 \). There are only outgoing edges from \( e_m \), which take to each of the other vertices of \( m \). Moreover, there is a transition from \( v_i \) to \( v_j \) for any \( i,j \in [n] \), and from any node there is a move to \( s \). Each node \( v_i \) is labeled with \( \sigma_i \) for \( i \in [n] \). The symbol \( \# \) labels \( e_m \) and \( s \).

As winning condition, we construct a deterministic pushdown automaton \( P \). In the initial state \( P \) reads \( \# \) and moves into state \( q_0 \). Fix \( i \in [2] \). From \( q_0 \) and on input \( a_i \), \( P \) enters state \( q_i \). From \( q_i \), \( P \) reads two occurrences of \( \# \) and enters the initial state of \( P_i \). From any \( P_i \) state, \( P \) behaves as \( P_i \), and in addition, from each final state of \( P_i \), it has a move on input \( \# \) that takes to the only final state \( q_f \).

Since the strategy must be modular, in the module \( m \) the player \( pl_0 \) has no information about the choice of \( pl_1 \) in \( m_{in} \). Also, the local strategy in module \( m \) generates one specific word (there are no moves of \( pl_1 \) allowed in \( m \)) and thus this is the same independently of the moves of \( pl_1 \) in module \( m_{in} \). Thus, the local strategy in \( m \) is winning if and only if it generates a word in the intersection of \( L_1 \) and \( L_2 \), and therefore, the following theorem holds.

**Theorem 1.** The (deterministic) pushdown modular game problem is undecidable.

### 4 Solving modular games with VPA specifications

**Visibly pushdown automata.** Consider the finite alphabet \( \Sigma \), and let \( call, ret, \) and \( int \) be new symbols. We denote with \( \Sigma_{call} = \Sigma \times \{call\}, \Sigma_{ret} = \Sigma \times \{ret\} \) and \( \Sigma_{int} = \Sigma \times \{int\} \) and with \( \tilde{\Sigma} = \Sigma_{call} \cup \Sigma_{ret} \cup \Sigma_{int} \).

A visibly pushdown automaton (VPA) \( P \) is a tuple \( (Q,Q_0,\tilde{\Sigma},\Gamma \cup \{\gamma^\bot\},\delta,F) \) where \( Q \) is a finite set of states, \( Q_0 \subseteq Q \) is a set of initial states, \( \tilde{\Sigma} \) is a finite alphabet, \( \Gamma \) is a finite stack alphabet, \( \gamma^\bot \) is the bottom-of-stack symbol, \( F \subseteq Q \) defines an acceptance condition, and \( \delta = \delta_{int} \cup \delta_{push} \cup \delta_{pop} \) where \( \delta_{int} \subseteq Q \times \Sigma_{int} \times Q, \delta_{push} \subseteq Q \times \Sigma_{call} \times \Gamma \times Q, \) and \( \delta_{pop} \subseteq Q \times \Sigma_{ret} \times (\Gamma \cup \{\gamma^\bot\}) \times Q \).

A configuration (or global state) of \( P \) is a pair \( (\alpha,q) \) where \( \alpha \in \Gamma^*.\{\gamma^\bot\} \) and \( q \in Q \). Moreover, \( (\alpha,q) \) is initial if \( q \in Q_0 \) and \( \alpha = \gamma^\bot \). We omit the semantics of the transitions of \( P \) being quite standard. It can be obtained similarly to that of RGG with the addition of the inputs. Here we just observe that we allow pop transitions on empty stack (a stack containing only the symbol \( \gamma^\bot \)). In particular, a pop transition do not change the stack when \( \gamma^\bot \) is at the top, and by the definition of \( \delta_{push} \), \( \gamma^\bot \) cannot be pushed onto the stack. A run \( \rho \) of \( P \) over the input \( \sigma_0 \sigma_1 \ldots \) is an infinite sequence \( C_0 \xrightarrow{\sigma_0} C_1 \xrightarrow{\sigma_1} \ldots \) where \( C_0 \) is the initial configuration and such that, for each \( i \in \mathbb{N} \), \( C_{i+1} \) is obtained from \( C_i \) by applying a transition on input \( \sigma_i \).
Acceptance of an infinite run depends on the control states that are visited infinitely often. Fix a run \( \rho = (\gamma^1, q_0) \xrightarrow{\sigma_0} (\alpha_1, q_1) \xrightarrow{\sigma_1} (\alpha_2, q_2) \ldots \). With a Büchi acceptance condition, \( \rho \) is accepting if \( q_i \in F \) for infinitely many \( i \in \mathbb{N} \) (Büchi VPA). With a co-Büchi acceptance condition, \( \rho \) is accepting if there is a \( j \in \mathbb{N} \) such that \( q_j \notin F \) for all \( i > j \) (co-Büchi VPA).

A VPA \( P \) is deterministic if: (1) \( |Q_0| = 1 \), (2) for each \( q \in Q \) and \( \sigma \in \Sigma_{\text{call}} \cup \Sigma_{\text{int}} \) there is at most one transition of \( \delta \) from \( q \) on input \( \sigma \), and (3) for each \( q_1 \in Q \), \( \sigma \in \Sigma_{\text{ret}} \), \( \gamma \in \Gamma \cup \{ \gamma^- \} \) there is at most one transition from \( q \) on input \( \sigma \) and stack symbol \( \gamma \). Note that a deterministic VPA is such that for each word \( w \) there is at most a run over it.

For a word \( w \), a deterministic/nondeterministic (resp. universal) VPA accepts \( w \) if there exists an accepting run over \( w \) (resp. all runs over \( w \) are accepting).

### Visibly pushdown games

A visibly pushdown game on RGG (VPRG) is a pair \( \langle G, P \rangle \) where \( G \) is an RGG and \( P \) is a visibly pushdown automaton (see [8]). Consider a VPRG \( \langle G, P \rangle \) where \( G \) is an RGG and \( P \) is a VPA. For a play \( \pi = s_0 s_1 \ldots \) of \( G \), with \( s_i = (\alpha_i, u_i) \), we define the word \( w_\pi \) as \( \sigma_0 \sigma_1 \ldots \) such that for \( i \in \mathbb{N} \), \( \sigma_i = (\eta_m(s_i), t_i) \) where \( \text{ctr}(\pi) = m \) and \( t_i \) is call if \( u_i \in \text{Calls} \), ret if \( u_i \in \text{Retns} \), and int otherwise. The visibly pushdown (modular) game problem asks to determine the existence of a (winning) modular strategy of \( pl_0 \) in a given VPRG such that \( w_\pi \) is accepted by \( P \) for every play \( \pi \) that conforms to \( f \). We denote the visibly pushdown modular game problem as MVPG problem.

When the VPA is a finite state automaton \( \mathcal{B} = (Q, q_0, \Sigma, \delta, F) \) we denote with \( \omega \)-MGP the \( \omega \)-modular game problem that asks to determine the existence of a winning modular strategy of \( pl_0 \) in a given \( \langle G, \mathcal{B} \rangle \) game (\( \omega \)-MG).

### Solving games with VPA specifications

We consider games with winning conditions that are given by a VPA with different acceptance conditions. We present a reduction from recursive games with VPA specifications to recursive games with specifications that are given as finite state automata. The reduction is almost independent of the acceptance condition, and it works for reachability and safety conditions as well as for Büchi and co-Büchi acceptance conditions.

The reduction transforms a recursive game graph with a visibly pushdown automaton specification (with some acceptance condition) to a slightly different recursive game graph with a finite-state automaton specification (with the same type of acceptance condition). The key idea is to embed the top stack symbol of a VPA \( P \) in the states of a finite-state automaton \( A \). In addition, the states of \( A \) will simulate the corresponding states of \( P \) and thus we will get that the winning conditions are equivalent. Clearly, a finite-state automaton cannot simulate an unbounded stack. While it is easy to keep track of the top symbol after a push operation, extracting the top symbol after a pop operation requires infinite memory. For this purpose we exploit the fact that the stacks of the VPA \( P \) and the game graph \( G \) are synchronized and we introduce a new dummy module \( d_m \) for every module in \( G \). Recall that the invocation of a module \( m \) in \( G \) correspond to a push operation in \( P \). We replace every invocation of \( m \) by a call to \( d_m \). In \( d_m \) (see Figure 3) \( pl_1 \) first has to declare the value of the top symbol in \( P \) before the push operation by going to the corresponding \( v_{\gamma_1}, \ldots, v_{\gamma_k} \) state in \( d_m \), and \( A \) can verify that \( pl_1 \) is honest since it keeps track of the current top-symbol (if the player is not honest then \( A \) goes to a sink accepting state and \( pl_1 \) loses). After the declaration, the

![Figure 3: The module \( d_m \). All the vertices of \( d_m \) are controlled by \( pl_1 \)](image)
module invokes the actual module \( m \) and when \( m \) terminates, then \( pl_1 \) must declare again the top-symbol \( \gamma \) of \( P \), visiting the vertex \( u_{\gamma} \), and \( A \) changes his simulated top symbol accordingly.

Denoting with \( k \) the number of exits of the starting RGG, with \( g \) the number of stack symbols, and \( d \) the number of states of the specification, we get that the resulting RGG \( G \) has \( 2^k \) exits and the resulting automaton \( A \) has \( O(dg) \) states. Thus combining this with the solution from [5], we get an upper bound linear in \( |G| \) and exponential in \( 2k(dg)^2 \log(2kdg) \). We have:

**Theorem 2.** The MVPG problem with winning conditions expressed as either a deterministic Büchi VPA or a deterministic co-Büchi VPA is EXPTIME-complete.

The proposed reduction can be extend for universal VPA specification. W.l.o.g we assume that in the non-deterministic VPA for every state, stack letter and labeling there are exactly two possible transitions. In this case we add a dummy module \( e \), that is composed only by \( pl_1 \) nodes and has one exit. Each transition from a node \( v \) to a node \( u \) is splitted in two transitions, \( v \rightarrow e \) and \( e \rightarrow u \). In the module \( e \), \( pl_1 \) resolves the nondeterminism, selecting one of the two possible transitions for the VPA specification. The choices of \( pl_1 \) in \( e \) are oblivious to \( pl_0 \). Hence, the universal VPA accepts if and only if \( pl_0 \) has a strategy that wins against all \( pl_1 \) choices in \( e \), and we get the next theorem.

**Theorem 3.** The MVPG problem with winning conditions expressed as a universal Büchi (resp. co-Büchi) VPA is EXPTIME-complete.

We can handle nondeterministic VPAs in the following way: Let \( P \) be a nondeterministic Büchi VPA \( P \). By [8], we can construct a nondeterministic Büchi VPA \( P' \) that accepts a word \( w \) iff \( P \) does not accept it, and such that the size of \( P' \) is exponential in the size of \( P \). Complete \( P' \) with transitions that take to a rejecting state such that for each word there is at least a run of \( P' \) over it. Let \( P'' \) be the dual automaton of \( P' \), i.e., \( P \) has the same components of \( P' \) except that acceptance is now universal and the set of accepting states is now interpreted as a co-Büchi condition. Clearly, \( P'' \) accepts exactly the same words as \( P \) and has size exponential in \( |P| \). Similarly, we can repeat the above reasoning starting from a co-Büchi VPA \( P \). Therefore, we have:

**Theorem 4.** The MVPG problem with winning conditions expressed as a nondeterministic Büchi (resp. co-Büchi) VPA is in 2EXPTIME.

5 Temporal logic winning conditions

By [3], we know that given a CARET formula \( \varphi \) it is possible to construct a nondeterministic Büchi VPA of size exponential in \( |\varphi| \) that accepts exactly all the words that satisfy \( \varphi \). From [1], we know that the same holds for the temporal logic NWTL. Thus, given a formula \( \varphi \) in any of the two logics, we construct a Büchi VPA \( P \) for its negation \( \neg \varphi \). By dualizing as in the case of nondeterministic VPA specifications, we get a co-Büchi VPA that accepts all the models of \( \varphi \) and which size is exponential in \( |\varphi| \). Since both CARET and NWTL subsume LTL [17], and LTL games are known to be 2EXPTIME-hard [18] already on standard finite game graphs, we get:

**Theorem 5.** The MVPG problem with winning conditions expressed as CARET and NWTL formulas is 2EXPTIME-complete.

The complexity of the temporal logic MVPG problem remains 2EXPTIME-hard even if we consider simple fragments.

A path formula is a formula expressing either the requirement that a given sequence appears as a subsequence in an \( \omega \)-word or its logical negation. Path formulas are captured by LTL formulas of the
form $\bigotimes (p_1 \land \bigotimes (p_2 \land \ldots \bigotimes (p_{n-1} \land \bigotimes p_n) \ldots))$ and by their logical negation, where each $p_i$ is state predicate. $\bigotimes \psi$ (eventually $\psi$) denotes that $\psi$ holds at some future position, and $\land$ is the Boolean conjunction. We denote such a fragment of LTL as PATH-LTL.

We present a reduction from exponential-space alternating Turing machines. We only give here the general idea. We use a standard encoding of computations, where cell contents are preceded by the cell number written in binary ($2N$ atomic propositions suffice to encode $2^N$ cell numbers) and configurations are sequences of cells encodings ended with a marker (the tape head and the current control state are encoded as cell contents).

Denote with $Q$ and $\Sigma$ respectively the control states and the input alphabet, and let $2^N$ be the number of cells used in each configuration. A configuration encoding is a sequence of the form $\langle 0 \rangle \sigma_0 \ldots (2^N) \sigma_{2^N}$ where there is a $i$ s.t. $\sigma_i \in Q \times \Sigma_i$ (this denotes the current state, the symbol of cell $i$ and that the tape head is on cell $i$), $\sigma_j \in \Sigma$ for all $j \neq i$ (symbol in cell $j$), and $\langle h \rangle$ is the binary encoding of $h$ (cell number) over new symbols $d^i_j$ and $d^i_r$ for $r \in [N]$ ($d^i_j$ is equivalent to 1 and $d^i_r$ to 0 in the binary encoding). A path of a computation (computations of alternating TM can be seen as trees of configurations) is encoded as a sequence $C_0d_0$ $\ldots$ $C_i d_i$ $\ldots$ where each $C_i$ is a configuration ($C_0$ is initial) and $d_i$ is the transition taken from $C_i$ to $C_{i+1}$.

We construct an RGG $G$ with two modules $M_{la}$ and $M_1$. In $M_{la}$, initially, $p_{l0}$ generates an encoding of an initial configuration, then, a transition is selected by $p_{l0}$, if the initial state is existential, or by $p_{l1}$, otherwise. In both cases, an end-of-configuration marker $\$ is generated and then $p_{l0}$ is in charge to generate again a configuration encoding, and so on. A call to $M_1$ is placed before generating the first cell encoding of each configuration and after generating each cell encoding. In $M_1$, $p_{l1}$ selects one among a series of actions that can either state that everything is fine (ok) or that some check is required (by raising one over nine objections). $M_1$ has only one exit.

The goal of $p_{l0}$ is to build an encoding of an accepting run of a TM $\mathcal{A}$ on a given input word, while the goal of $p_{l1}$ is to point out errors in such encoding by raising objections to delimit the cell encodings where the check has to take place. There are two possible mistakes that can occur: the $i$th cells of two consecutive configurations do not conform the transition relation of $\mathcal{A}$ and the number of a cell is not the successor of the number of the preceding cell in the configuration. We use separate groups of objections to point out each of these mistakes. These specifications can be captured with a formula $\varphi$ defined as $
abla \neg \text{obj} \lor (\psi_{wl1} \lor \psi_\Delta \land (\psi_{wr2} \lor \psi_3)) \lor (\bigotimes \text{obj} \lor \bigotimes F)$ where: (1) $\text{obj}$ denotes that an objection has been raised; (2) $F$ denotes a state predicate that is true on symbols of the encoding that correspond to final states of $\mathcal{A}$; (3) $\psi_{wl1}$ and $\psi_{wr2}$ capture all the illegal uses of respectively the first and the second type of objections; (4) $\psi_\Delta$ checks the transition relation between two consecutive configurations on the cells selected by the raised objections of type 1; and (5) $\psi_3$ checks the correct encoding of the cell numbers of two consecutive cells selected by the raised objections of type 2. All the above formulas can be written with disjunctions of path formulas except for $\psi_3$ that is a conjunction of disjunctions of path formulas. Using De Morgan laws, the total formula can be transformed into an equivalent formula of size polynomial in $|\varphi|$, which is a disjunction of conjunctions of path formulas. Also note that all the used path formulas are of bounded size (the most complex one uses eleven occurrences of $\bigotimes$). Moreover, in a modular strategy $p_{l0}$ cannot use the fact that $p_{l1}$ has raised an objection to decide the next move since the objections are raised in a different module (which has just one exit). Therefore, in order to win, $p_{l0}$ must correctly generate the computations of the TM. We get the following:

**Lemma 6.** The MVPG problem with winning conditions expressed as a conjunction of disjunctions of bounded-size PATH-LTL formulas is 2EXPTIME-hard.

It is known that each formula $\varphi$ from PATH-LTL admits a deterministic Büchi word automaton accepting all the models of $\varphi$ and which is linear in its size [4]. The same can be shown with Büchi
VPA, by extending PATH-LTL allowing the versions of the ◇ operator of CARET and NWTL. By the closure properties of universal visibly pushdown automata we can easily extend Theorem 3 to winning conditions given as intersection of deterministic VPAs and thus:

**Theorem 7.** The MVPG problem with winning conditions expressed as a conjunction of CARET and NWTL formulas that admit a deterministic Büchi or co-Büchi VPA generator of polynomial size is EXPTIME-complete.

Now consider the larger fragment of formulas $\bigwedge_{i=1}^{h} \bigwedge_{j=1}^{v} \varphi_{i,j}$ where for each $\varphi_{i,j}$ we can construct either a deterministic Büchi or a deterministic co-Büchi VPA $P_{i,j}$ of polynomial size that generates all the models of $\varphi_{i,j}$. We are only able to show an EXPTIME lower bound using a construction similar to that used in the reduction of Lemma 6 However, we observe that a matching upper bound cannot be shown using automata constructions, since we would need to manage the union of $N$ specifications without an exponential blow-up, and since intersection is easy, this would contradict Lemma 6.

6 Improving the tree automata construction to solve $\omega$-MGP with Büchi condition

We assume the standard definitions of trees and nondeterministic/universal tree automata with Büchi and co-Büchi acceptance (universality refers to the fact that all runs must be accepting in order to accept. See [5] for definitions).

**General structure of the construction.** Fix a $\omega$-MG $(G, B)$ where $B = (Q, q_0, \Sigma, \delta, F)$ is a deterministic Büchi automaton and $G$ is as in Section 2. We construct a Büchi tree automaton $A_{G, B}$ that accepts a tree if and only if $p_{q_0}$ has a winning modular strategy in the game $(G, B)$.

The trees accepted by $A_{G, B}$ must encode $G$ and a modular strategy on it (strategy trees). Each such tree essentially has a subtree rooted at a child of the root for each module of $G$ and each such subtree is the unwinding of the corresponding module along with a labeling encoding the strategy.

The general idea is to check on each subtree of the root some properties of the corresponding local function of the encoded modular strategy, by assuming some other properties on the local functions of the other modules (as in an assume-guarantee reasoning). These assumptions concern: a call structure $CG$ (Büchi call graph), to handle acceptance on plays involving infinitely many unreturned calls; a set $E$ for each module, each giving a superset of the exits that can be visited during the plays; a set of extended pre-post conditions $C$, that for each module $m$, each exit $x$ and each possible state $q$ of $B$, carries the requirement that if $m$ is entered with $q$ and the play exits at $x$, then this must happen with state $q'$ such that $(m, q, x, q') \in C$ and after visiting an accepting state if this is required by $C$. To ensure correctness all modules must share the same assumptions, thus $A_{G, B}$ guesses the assumptions at the root and then passes them onto the children of the root.

The tasks of $A_{G, B}$ thus are: recognizing the strategy trees; ensuring the correctness of the extended pre-post conditions; ensuring that all the plays according to the modular strategy conform the Büchi call graph and do not exit a module from an exit different from those listed in $C$; checking the acceptance condition of $B$ on all the plays encoded in the strategy tree, using the pre-post condition, the acceptance condition of $B$ and the Büchi call graph.

The above tasks are split among the Büchi tree automata $A_G$, $A_{CG}$, and $A_{B,F,C,CG}$. The automata $A_G$ and $A_{CG}$ are nondeterministic and check the fulfillment of the properties related to the game graph, $A_G$ is in charge of verifying that the input tree is a valid strategy tree. $A_{CG}$ is parameterized over the set of exits $E$ and a Büchi call graph $CG$. The automaton $A_{B,F,C,CG}$, which is a universal Büchi tree
automaton, checks the extended pre-post condition $\mathcal{E}$, simulates $\mathcal{B}$ and checks the fulfillment of its winning conditions.

$\mathcal{A}_{G,\mathcal{B}}$ captures the intersection of $\mathcal{A}_G$ and the automaton that, at the root, nondeterministically guesses $\mathcal{E}, CG, \mathcal{E}$, and then at the children of the root, captures the intersection of $\mathcal{A}_{\mathcal{B}, \mathcal{E}, CG}$ and $\mathcal{A}_{CG}$.

The automaton $\mathcal{A}_G$. Let $k$ be the maximum over the number of exits of $G$ modules and the out-degree of $G$ vertices. Denote with $\Omega_G$ the set $\{\text{dummy}, \text{root}\} \cup (V \setminus P^0) \cup (P^0 \times [k])$ (recall $V$ denotes the set of vertices of $G$). $\mathcal{A}_G$ accepts strategy trees, i.e., $\Omega_G$-labeled $k$-trees that encode modular strategies of $pl_0$.

Intuitively, in a strategy tree, the label root is associated with the root of the tree. The children of the root are labeled with the entries of each module in $G$. A subtree rooted in one of these vertices corresponds to the unrolling of a module. If a vertex is labeled with a node that belongs to $pl_0$, the move according to the encoded strategy is annotated with the index of the selected successor. If a node is associated to a call, then its children are labeled with the matching returns. The dummy nodes are used to complete the $k$-tree. A similar formal definition is given [5].

In Fig. 4 we depict the top fragment of a strategy tree for $pl_0$ of the RGG from Fig. 1.

![Figure 4: A fragment of a strategy tree.](image)

Given a tree $T$, the automaton $\mathcal{A}_G$ accepts $T$ iff it is a strategy tree for $G$. A construction for $\mathcal{A}_G$ can be easily obtained from $G$, and thus we omit it (see [3] for a similar construction).

Proposition 8. There exists an effectively constructible Büchi tree automaton of size $O(|G|)$ that accepts a $\Omega_G$-labeled $k$-tree if and only if it is a strategy tree.

Directly from the definitions, the following holds:

Proposition 9. For a $\omega$-MG and fixed a player $pl$, there exists a one-to-one mapping between the modular strategies of $pl$ and the strategy trees.

The automaton $\mathcal{A}^f_{CG}$. Fix a modular strategy $f$ of $pl_0$ in $G$. A call graph (of $G$) according to $f$ is a directed graph $\langle V, \rightarrow \rangle$, $V \subseteq M$, such that for each play $\pi$ which conforms to $f$, if a module $m \in M$ is reachable on $\pi$ then $m \in V$ and if a call from $m'$ to $m''$ is done on $\pi$ then $m' \rightarrow m''$ holds.

A Büchi call graphs $CG$ of $G$ according to $f$ and $\mathcal{B}$ is $\langle V, \rightarrow, \rightarrow_F \rangle$ where $V \subseteq M \times Q$, $\rightarrow_F \subseteq \rightarrow$ and:

1. denoting with $\xi((m, q)) = m$, the graph defined by all the edges $\xi(v) \to' \xi(v')$ s. t. $v \to v'$ is a call graph of $G$ according to $f$ (denoted $\xi(CG)$ in the following), and
2. for each cycle $v_1 \rightarrow v_2 \rightarrow \ldots \rightarrow v_h \rightarrow v_{h+1}$ (with $v_1 = v_{h+1}$), there exists at least a $j \in [1, h]$ such that $(v_j \rightarrow_F v_{j+1})$ (in order to fulfill a Büchi condition, in a cycle of calls there must exist at least a module $m_j$ among $m_{i_1}, \ldots, m_{i_h}$ in which an $F$ state of $\mathcal{B}$ is visited infinitely often).

In a strategy tree, a node is enabled if it is the root or the corresponding vertex of $G$ is reachable in the encoded strategy. For a given Büchi call graph $CG$ and a selection of exits $\mathcal{E}$, by assuming that the input tree is a strategy tree, the automaton $\mathcal{A}^f_{CG}$ checks that indeed the input tree conforms to $CG$ and $\mathcal{E}$.

Lemma 10. There exists an effectively constructible Büchi tree automaton $\mathcal{A}^f_{CG}$ such that if $T$ is a strategy tree of $G$ and $f$ is the corresponding modular strategy, then $\mathcal{A}^f_{CG}$ accepts $T$ unless either (1) an exit not in $\mathcal{E}$ is enabled, or (2) $\xi(CG)$ is not a call graph of $G$ according to $f$ (i.e., there exists an enabled call from $m$ to $m'$ but no edge from $m$ to $m'$ in $\xi(CG)$). The size of $\mathcal{A}^f_{CG}$ is linear in $|G|$.
The automaton $\mathcal{A}_{g,C}$. The automaton $\mathcal{A}_{g,C}$ is parameterized over the Büchi automaton $B$, an extended pre-post condition $C$ (which essentially summarizes the effects of $B$ executions in each module of $G$) and a Büchi call-graph $CG$. It is quite complex and its tasks are:

1. to simulate $B$ on a strategy tree (and in this, it uses $C$ s.t. when simulating $B$ in a module it is not needed to follow the calls to other modules and the simulation can continue at a matching return);
2. to check the correctness of the pre-post condition $C$;
3. to check that the accepting states of $B$ are entered consistently with $CG$ on the cycles of calls;
4. to check the fulfillment of $B$ acceptance conditions.

We first construct an automaton $\xi$ which ensures task 1, then on the top of $\mathcal{A}_{g,C}$ we construct three different automata $\mathcal{A}_{g,C}, \mathcal{A}_{g,CG}$ and $\mathcal{A}_{g,\text{min}}$, one for each of the remaining three tasks. We then get $\mathcal{A}_{g,C,CG}$ by taking the usual cross product for the intersection of these automata (note that an efficient construction can be obtained by discarding all the states that do not agree on the $\mathcal{A}_{g,C}$ part, thus avoiding a cubic blow-up in the size of $\mathcal{A}_{g,C}$). Under the assumption that the input tree is a strategy tree and $\xi(CG)$ is consistent with it, we get that $\mathcal{A}_{g,C,CG}$ accepts only winning strategy trees (i.e., strategy trees that correspond to winning modular strategies) that conform to $CG$ and $C$. The details on all the above automata are given in the rest of this section. Thus, we get:

**Lemma 11.** Let $\langle G, B \rangle$ be a $\omega$-MG and $\mathcal{B}$ be a Büchi automaton. Given a Büchi call graph $CG$ and a pre-post condition $C$, there exists an effectively constructible universal Büchi tree automaton $\mathcal{A}_{g,C,CG}$ s.t.: if $T$ is a strategy tree of $G$, $f$ is the corresponding modular strategy and $\xi(CG)$ is a call graph of $G$ according to $f$, then $\mathcal{A}_{g,C,CG}$ accepts $T$ iff $T$ is winning in $\langle G, B \rangle$ and consistent with $CG$ and $C$. The size of $\mathcal{A}_{g,C,CG}$ is quadratic in the number of $B$ states.

**Winning strategy trees.** For a strategy tree $T$ of $G$, a play of $T$ is an $\omega$-sequence of $T$-nodes $v_1\ldots$ such that $v_1$ is the child of the root corresponding to $m_{\text{in}}$, $\alpha_1 = \epsilon$ (call-stack) and for $i \in \mathbb{N}$, $v_i$ is an enabled node and: (1) if $v_i$ is labeled with a call to $m$, then $v_{i+1}$ is the child of the $T$ root corresponding to module $m$ (and thus is labeled with the entry $e_m$), and $\alpha_{i+1} = \alpha_i v_i$; (2) if $v_i$ is labeled with an exit $ex$, then $\alpha_i = \alpha_{i+1} v_i y$, $y$ is a node labeled with a call $(b, e_m)$ and $v_{i+1}$ is the child of $y$ labeled with the return $(b,ex)$; (3) otherwise, $v_{i+1}$ is an enabled child of $v_i$ and $\alpha_{i+1} = \alpha_i$.

Note that any play of a strategy tree $T$ corresponds to a play of $G$ (conforming to the modular strategy defined by $T$). A winning strategy tree $T$ w.r.t. $B$ is such that for all the plays $v$ of $T$, $w_v$ is accepted by $B$. From Proposition 9 we get:

**Lemma 12.** Given a $\omega$-MG $\langle G, B \rangle$, a modular strategy is winning iff the corresponding strategy tree is winning.

**Pre-post conditions.** A pre-post condition on the graph $G$ is a pair $\langle C_{\text{pre}}, C_{\text{post}} \rangle$ where $C_{\text{pre}} \subseteq M \times Q$ (set of pre-conditions), $C_{\text{post}} \subseteq M \times Q \times Ex \times Q$ (set of pre-post conditions), and such that for each $(m, q, ex, q') \in C_{\text{post}}$, also $(m, q) \in C_{\text{pre}}$ (i.e., tuples of $C_{\text{post}}$ add a post-condition to some of the pre-conditions of $C_{\text{pre}}$).

Intuitively, a pre-post condition is meant to summarize all the $B$ locations that can be reached on entering each module of $G$ along any play of $T$, and for each reachable exit $ex$, all the pairs of $B$ locations $(q, q')$ s.t. there exists a play of $T$ along with $B$ enters a module at $q$ and exits it from $ex$ at $q'$.

Fix a pre-post condition $\langle C_{\text{pre}}, C_{\text{post}} \rangle$. $\langle C_{\text{pre}}, C_{\text{post}} \rangle$ is consistent with a strategy tree $T$ if for each play $v = v_1 v_2\ldots$ of $T$ and for each $v_i$ which is labeled with a call to module $m \in M$, denoting with $q$ the location at which the only run of $B$ over $w_{v_i}$
ends: (1) \((m,q)\) belongs to \(\mathcal{C}_{\text{pre}}\) and (2) if \(v\) reaches the matching return at \(x_{j+1}\), \(x_j\) is labeled with exit \(ex\) and the location at which the run of \(\mathcal{B}\) over \(w_{v_{j1}}\) is \(q'\) (i.e., the location when reading the symbol of \(ex\) at \(x_j\)), then \((m,q,ex,q')\) belongs to \(\mathcal{C}_{\text{post}}\).

\(\langle \mathcal{C}_{\text{pre}}, \mathcal{C}_{\text{post}} \rangle\) is consistent with a set of exits \(\langle \mathcal{E}^m \rangle_{m \in M}\) iff: (1) \(\forall m \in M, \forall ex \in \mathcal{E}^m\), if there is a \((m,q) \in \mathcal{C}_{\text{pre}}\) then there is at least a tuple of the form \((m,q,ex,q') \in \mathcal{C}_{\text{post}}\); (2) \(\forall (m,q,ex,q') \in \mathcal{C}_{\text{post}}\), then \(ex \in \mathcal{E}^m\) holds.

We extend pre-post conditions with a function \(\text{Fin} : \mathcal{C}_{\text{post}} \rightarrow \{true, false\}\). An extended pre-post condition \(\mathcal{C} = \langle \mathcal{C}_{\text{pre}}, \mathcal{C}_{\text{post}}, \text{Fin} \rangle\) is consistent with a strategy tree \(T\) if \(\langle \mathcal{C}_{\text{pre}}, \mathcal{C}_{\text{post}} \rangle\) is consistent with \(T\) and for each play \(v = x_{1}x_{2} \ldots \) of \(T\) s.t. \(x_{j}\) is labeled with a call to module \(m \in M\), \(x_{j-1}\) is labeled with its matching return, and the portion of run of \(\mathcal{B}\) from \(i\) to \(j\) starts at location \(q\) and ends at location \(q'\): whenever \(\text{Fin}(m,q,ex,q') = true\) then a location in \(F\) must be visited on this portion of run (acceptance-condition).

**Construction of \(\mathcal{A}_{\mathcal{B}}\).** Fix an extended pre-post condition \(\mathcal{C} = \langle \mathcal{C}_{\text{pre}}, \mathcal{C}_{\text{post}}, \text{Fin} \rangle\). Let \(m_i\) be the module mapped to the \(i^{th}\) child of the root of a strategy tree.

We construct \(\mathcal{A}_{\mathcal{B}}\) such that the automaton simulates \(\mathcal{B}\) on an input strategy tree \(T\) by using \(\mathcal{C}\). In particular, starting from the \(i^{th}\) child, the automaton \(\mathcal{A}_{\mathcal{B}}\) runs in parallel a copy of \(\mathcal{B}\) from each control state \(q\) such that \((m_i,q) \in \mathcal{C}_{\text{pre}}\). When reading a node labeled with a call, \(\mathcal{A}_{\mathcal{B}}\) starts at each matching return a copy of \(\mathcal{B}\) according to the applicable tuples in \(\mathcal{C}\) and performs updates according to \(\text{Fin}\). On all the other enabled nodes, the control state of \(\mathcal{B}\) is updated for each copy according to \(\mathcal{B}\) transitions.

The states of \(\mathcal{A}_{\mathcal{B}}\) are: an initial state \(q_0\), an accepting state \(q_a\), a rejecting state \(q_r\), and states of the form \((q,d,f,q_{m_i},\mathcal{C})\) where \(q,q_{m_i} \in Q\), \(q\) is the control state which is updated in the simulation of \(\mathcal{B}\), \(q_{m_i}\) is the current pre-condition, and \(d,f \in \{0,1\}\) are related to the winning conditions. Namely, \(d\) is used to check the acceptance-conditions along all the plays that conform to the strategy, and \(f\) is used to expose that a final state of \(\mathcal{B}\) was seen between a call and its matching return. A task of \(\mathcal{A}_{\mathcal{B}}\) is to handle the correct update of these bits, but they will be used to determine the acceptance by \(\mathcal{A}_{\mathcal{B}_{\text{win}}}\). The states \(q_a\) and \(q_r\) are sinks, i.e., once reached, the automaton cycles forever on them.

**Construction of \(\mathcal{A}_{\mathcal{B},\mathcal{C}G}\) and \(\mathcal{A}_{\mathcal{B}_{\text{win}}}\).** The automaton \(\mathcal{A}_{\mathcal{B},\mathcal{C}G}\) is in charge of checking that the input tree is consistent with the extended pre-post condition \(\mathcal{C}\). We construct it from \(\mathcal{A}_{\mathcal{C}G}\) by modifying the transitions from a state \(s\) of the form \((q,d,f,q_{m_i},\mathcal{C})\) at a tree-node labeled with an exit. In particular, in this case, we let \(\mathcal{A}_{\mathcal{B},\mathcal{C}G}\) enter \(q_a\) if there exists a tuple \((m_i,q_{m_i},ex_h,q) \in \mathcal{C}_{\text{post}}, \text{and } q_r\) otherwise.

The purpose of \(\mathcal{A}_{\mathcal{B},\mathcal{C}G}\) is to check that the Büchi call graph \(CG\) is indeed consistent with the input strategy tree. We construct \(\mathcal{A}_{\mathcal{B},\mathcal{C}G}\) from \(\mathcal{A}_{\mathcal{B}}\) by modifying the transitions from calls. Namely, when on a node \(u\) labeled with a call to a module \(m_j\) in the subtree of the \(i^{th}\) child of the root, at a state of the form \((q',d,f,q',\mathcal{C}')\) and suppose there is a transition \((q',\eta_m(u),q'') \in \mathcal{E}\): if \(m_i \rightarrow_F m_j \rightarrow_F \mathcal{C}\) holds in the Büchi call graph \(CG\) and \(d = 0\), then \(\mathcal{A}_{\mathcal{B},\mathcal{C}G}\) enters the rejecting state \(q_r\). In all the other cases it behaves as \(\mathcal{A}_{\mathcal{C}G}\).

The purpose of \(\mathcal{A}_{\mathcal{B}_{\text{win}}}\) is to check that the winning conditions of \(\mathcal{B}\) are satisfied along all plays of the input strategy tree. Again, we can modify \(\mathcal{A}_{\mathcal{C}G}\) to ensure this. In particular, when the automaton reaches a tree-node labeled with exit \(ex\) of module \(m\) in a state \((q',d,f,q',\mathcal{C}')\), then it enters the accepting state \(q_a\), whenever \((m,q,ex,q') \in \mathcal{C}_{\text{post}}\) and \(\text{Fin}(m,q,ex,q') = true\) implies \(b = 1\), and \(q_r\) otherwise. Moreover the accepting states of \(\mathcal{A}_{\mathcal{B}_{\text{win}}}\) are \(q_a\) and all the states of the form \((q',d,f,q',\mathcal{C}')\) such that either \(q \in F\) or \(f = 1\).

**Reducing to emptiness of Büchi tree automata.** \(\mathcal{A}_{\mathcal{B},\mathcal{C}G}\) can be translated into an equivalent non-deterministic Büchi tree automaton with \(2O(|Q|^2 \log |Q|)\) states [16]. Denoting with \(k\) the number of \(G\) exits
and $\beta$ the number of call edges of $G$ (i.e., the number of module pairs $(m,m')$ such that there is a call from $m$ to $m'$), the number of different choices for an extended post-pre condition is $2^{O(k|Q|^2)}$, for a Büchi call graph is $2^{|Q|^{\beta}}$, and for a set of exits $E$ is $2^{|E|}$. Since $A_G$ and $A_{CG}$ are both of size $O(|G|)$, the automaton $A_{G,\mathcal{B}}$ (obtained as described earlier in this section) is of size $|G|^2 2^{O(|Q|^{2(k + \log |Q|) + \beta})}$. We can reduce the factor $|G|^2$ to $|G|$, by combining $A_G$ and $A_{CG}$ into the same automaton (they are essentially based on $G$ transitions). Therefore, we can get an efficient construction of $A_{G,CG}$ of size $|G| 2^{O(|Q|^{2(k + \log |Q|) + \beta})}$. Thus, by Propositions 8 and 9, and Lemmas 10 and 11.

**Theorem 13.** For an RGG $G$ and a deterministic Büchi automaton $\mathcal{B}_p$ has a winning modular strategy in $\langle G, \mathcal{B}\rangle$ if and only if the nondeterministic Büchi tree automaton $A_{G,\mathcal{B}}$ accepts a non-empty language. Moreover, $A_{G,\mathcal{B}}$ is of size $|G| 2^{O(|Q|^{2(k + \log |Q|) + \beta})}$, where $k$ is the number of $G$ exits.

7 Discussion

In this paper, we have considered modular games with winning condition expressed by pushdown, visibly pushdown and temporal logic specifications. We have proved that the modular game problem with respect to standard pushdown specifications is undecidable. Then we have presented a number of results that give a quite accurate picture of the computational complexity of the MVPG problem with visibly pushdown winning conditions. With some surprise, we have found that MVPG with temporal logic winning conditions becomes immediately hard. In fact, while the complexity for LTL specifications is 2EXPTIME-complete both for MVPG and games on finite graphs, for the fragment consisting of all the Boolean combinations of PATH-LTL formulas, solving the corresponding games on finite graphs is PSPACE-complete while the MVPG problem is already 2EXPTIME-complete. As a consequence, the computational complexity of many interesting fragments of LTL, that have a better complexity than full LTL on finite game graphs, collapses at the top of the complexities (see [4, 6]). This also differs with the scenario of the complexities of model-checking RSMs in LTL fragments (see [12]). As a final remark, we observe that the tree automaton construction proposed in Section 6 can be easily adapted to handle visibly pushdown winning conditions to get a direct solution of the MVPG problem. We only need to modify the transition rules to synchronize the calls and returns of the RGG with the pushes and pops of the specification automaton, and this would be possible since they share the same visibly alphabet. The change does not affect the overall complexity, however it will slightly improve on the approach presented in Section 4 that causes doubling the number of exits and gives a complexity with an exponential dependency in the number of stack symbols.
