We present the Geometric-Wave Acoustic (GWA) dataset, a large-scale audio dataset of about 2 million synthetic room impulse responses (IRs) and their corresponding detailed geometric and simulation configurations. Our dataset samples acoustic environments from over 6.8K high-quality diverse and professionally designed houses represented as semantically labeled 3D meshes. We also present a novel real-world acoustic materials assignment scheme based on semantic matching that uses a sentence transformer model.

We compute high-quality impulse responses corresponding to accurate low-frequency and high-frequency wave effects by automatically calibrating geometric acoustic ray-tracing with a finite-difference time-domain wave solver. We demonstrate the higher accuracy of our IRs by comparing with recorded IRs from complex real-world environments. Moreover, we highlight the benefits of GWA on audio deep learning tasks such as automated speech recognition, speech enhancement, and speech separation. This dataset is the first data with accurate wave acoustic simulations in complex scenes. Codes and data are available at https://gamma.umd.edu/pro/sound/gwa.

1 INTRODUCTION
Audio signals corresponding to music, speech, and non-verbal sounds in the real world encode rich information regarding the surrounding environment. Many digital signal processing algorithms and audio deep learning techniques have been proposed to extract information from audio signals. These methods are widely used for different applications such as music information retrieval, automated speech recognition, sound separation and localization, sound synthesis and rendering, etc.

Many audio processing tasks have seen rapid progress in recent years due to advances in deep learning and the accumulation of large-scale audio or speech datasets. Not only are these techniques widely used for speech processing, but also acoustic scene understanding and reconstruction, generating plausible sound effects for interactive applications, audio synthesis for videos, etc. A key factor in the advancement of these methods is the development of audio datasets. There are many datasets for speech processing, including datasets with different settings and languages [Park and Mulk 2019], emotional speech [Tits et al. 2019], speech source separation [Drude et al. 2019], source sound localization [Wu et al. 2018], noise suppression [Reddy et al. 2020], background noise [Reddy et al. 2019], music generation [Briot et al. 2017], etc.

In this paper, we present a large, novel dataset corresponding to synthetic room impulse responses (IRs). In the broader field of acoustical analysis, the IR is defined as the time domain (i.e. time vs amplitude) response of a system to an impulsive stimulus [Kuttruff 2016]. It is regarded as the acoustical signature of a system and contains information related to reverberant, signal-to-noise ratio, arrival time, energy of direct and indirect sound, or other data related to acoustic scene analysis. These IRs can be convolved with anechoic sound to generate artificial reverberation, which is widely used in music, gaming and VR applications. The computation of accurate IRs and resulting datasets are used for the following areas:

Sound Propagation and Rendering. Sounds in nature are produced by vibrating objects and then propagate through a medium (e.g., air) before finally being heard by a listener. Humans can perceive these sound waves in the frequency range of 20Hz to 20KHz (human aural range). There is a large body of literature on modeling sound propagation in indoor scenes using geometric and wave-based methods [Allen and Raghuvanshi 2015; Funkhouser et al. 1998; Krokstad et al. 1968; Liu and Manocha 2020; Mehra et al. 2013; Raghuvanshi et al. 2009; Schissler et al. 2014; Vorländer 1989]. Wave-based solvers are expensive for high-frequency sound propagation. As approximations, Wang et al. [2018] use full wave simulation to model local sound synthesis followed by estimated far-field sound radiation, while Chattanya et al. [2020] pre-compute and encode static sound fields using psycho-acoustic parameters. Geometric methods, widely used in interactive applications, are accurate for higher frequencies. We need automatic software systems that can accurately compute IRs corresponding to human aural range and handle arbitrary 3D models.

Deep Audio Synthesis for Videos. Video acquisition has become very common and easy. However, it is hard to add realistic audio that can be synchronized with animation in a video. Many deep learning methods have been proposed for such audio synthesis that utilize acoustic impulse responses for such applications [Li et al. 2018; Owens et al. 2016; Zhou et al. 2018].

Speech Processing using Deep Learning. IRs consist of many clues related to reproducing or understanding intelligible human speech. Synthetic datasets of IRs have been used in machine learning methods for automatic speech recognition [Ko et al. 2017; Malik et al. 2021; Ratnarajah et al. 2021; Tang et al. 2020b], sound source separation [Aralikatti et al. 2021; Jenrungrot et al. 2020] and sound source localization [Grumiaux et al. 2021].

Sound Simulation using Machine Learning. Many recent deep learning methods have been proposed for synthetic sound [Hawley et al. 2020; Ji et al. 2020; Jin et al. 2020], scattering effect computation, and sound propagation [Fan et al. 2020; Pulikki and Svensson 2019; Tang et al. 2021]. Deep learning methods have also been used to compute material properties of a room and acoustic characteristics [Schissler et al. 2017; Tang et al. 2020a].

Other applications that have used acoustic datasets include navigation [Chen et al. 2020], floorplan reconstruction [Purushwalkam et al. 2021] and depth estimation algorithms [Gao et al. 2020].

There are some known datasets of recorded IRs from real-world scenes and synthetic IRs (see Table 1). The real-world datasets are limited in terms of number of IRs or the size and characteristics of the captured scenes. All prior synthetic IR datasets are generated using geometric simulators and do not accurately capture low-frequency wave effects. This limits their applications.

Main Results. We present the first large acoustic dataset (GWA) of synthetically generated IRs that uses accurate wave acoustic simulations in complex scenes. Our approach is based on using a hybrid simulator that combines a wave-solver based on finite differences time domain (FDTD) method with geometric sound propagation based on path tracing. The resulting IRs are accurate over the human aural range. Moreover, we use a large database of more than 6.8K professionally designed scenes with more than 18K rooms with furniture that provide a diverse set of geometric models. We present a novel and automatic scheme for semantic acoustic material assignment based on natural language processing techniques. We use a database of absorption coefficients of 2,042 unique real-world materials and use a transformer network for semantic material selection. Currently, GWA consists of more than 2 million IRs. We can easily use our approach to generate more IRs by either changing the source and receiver positions or using different set of geometric models or materials. The novel components of our work include:

- Our dataset has more acoustic environments than real-world IR datasets by two orders of magnitude.
- Our dataset has more diverse IRs with higher accuracy, as compared to prior synthetic IR datasets.
Table 1: Overview of some existing large IR datasets and their characteristics. In the “Type” column, “Rec.” means recorded and “Syn.” means synthetic. The real-world synthetic datasets capture the low-frequency (LF) and high-frequency (HF) wave effects in the recorded IRs. Note that all prior synthetic datasets use geometric simulation methods and are accurate for higher frequencies only. In contrast, we use an accurate hybrid geometric-wave simulator on more diverse input data, corresponding to professionally designed 3D interior models with furniture, and generate accurate IRs corresponding to the entire human aural range (LF and HF). We highlight the benefits of our high-quality dataset for different audio and speech applications.

| Dataset          | Type  | #IRs | #Scenes | Scene Descriptions   | Scene Types | Acoustic Material | Quality |
|------------------|-------|------|---------|----------------------|-------------|------------------|---------|
| BIU [Hadad et al. 2014] | Rec.  | 234  | 3       | Photos               | Acoustic lab | Real-world       | LF, HF  |
| MeshIRR [Koyama et al. 2021] | Rec.  | 4.4K | 2       | Room dimensions      | Acoustic lab | Real-world       | LF, HF  |
| BUT Reverb [Szöke et al. 2019] | Rec.  | 1.3K | 8       | Photos               | Various sized rooms | Real-world | LF, HF  |
| 53A [Coleman et al. 2020] | Rec.  | 1.6K | 5       | Room dimensions      | Various sized rooms | Real-world | LF, HF  |
| dEchorate [Carlo et al. 2021] | Rec.  | 2K   | 11      | Room dimensions      | Acoustic lab | Real-world       | LF, HF  |
| Ko et al. [2017] | Syn.  | 60K  | 600     | Room dimensions      | Empty shoebox rooms | Uniform sampling | HF      |
| BIRD [Grondin et al. 2020] | Syn.  | 100K | 100K    | Room dimensions      | Empty shoebox rooms | Uniform sampling | HF      |
| SoundSpaces [Chen et al. 2020] | Syn.  | 16M  | 101     | Annotated 3D model   | Scanned indoor scenes | Material database | HF      |
| GWA (ours)       | Syn.  | 2M   | 18.9K   | Annotated 3D model   | Professionally designed | Material database | LF, HF  |

- The accuracy improvement of our hybrid method over prior methods is evaluated by comparing our IRs with recorded IRs of multiple real-world scenes.
- We use our dataset to improve the performance of deep-learning speech processing algorithms, including automatic speech recognition, speech enhancement, and source separation, and observe significant performance improvement.

2 DATASET CREATION

A key issue in terms of the design and release of an acoustic dataset is the choice of underlying 3D geometric models. Given the availability of interactive geometric acoustic simulation software packages, it is relatively simple to randomly sample a set of simple virtual shoebox-shaped rooms for source and listener positions and generate unlimited simulated IR data. However, the underlying issue is such IR data will not have the acoustic variety (e.g., room equalization, material diversity, wave effects, reverberation patterns, etc.) frequently observed in real-world datasets. We identify several criteria that are important in terms of creating a useful synthetic acoustic dataset: (1) a wide range of room configurations: the room space should include regular and irregular shapes as well as furniture placed in reasonable ways. Many prior datasets are limited to rectangular, shoebox-shaped or empty rooms (see Table 1); (2) meaningful acoustic materials: object surfaces should use physically plausible acoustic materials with varying absorption and scattering coefficients, rather than randomly assigned frequency-dependent coefficients; (3) an accurate simulation method that accounts for various acoustic effects, including specular and diffuse reflections, occlusion, and low-frequency wave effects like diffraction. It is important to generate IRs corresponding to the human aural range for many speech processing and related applications. In this section, we present our pipeline for developing a dataset that satisfies all these criteria. An overview of our pipeline is illustrated in Figure 1.

2.1 Acoustic Environment Acquisition

Acoustic simulation for 3D models requires that environment boundaries and object shapes be well defined. This requirement can often be fulfilled by 3D meshes. Simple image-method simulations may only require a few room dimensions (i.e., length, width, and height) and have been used for speech applications, but these methods cannot handle complex 3D indoor scenes. Many techniques have been proposed in computer vision to reconstruct large-scale 3D environments using RGB-D input [Choi et al. 2015]. Moreover, they can be combined with 3D semantic segmentation [Dai et al. 2018] to recover category labels of objects in the scene. This facilitates the collection of indoor scene datasets. However, real-world 3D scans tend to suffer from measurement noise, resulting in incomplete/discontinuous surfaces in the reconstructed model that can be problematic for acoustic simulation algorithms. One alternative is to use professionally designed scenes of indoor scenes in the form of CAD models. These models are desirable for acoustic simulation because they have well-defined geometries and the most accurate semantic labels. Therefore, we use CAD models from the 3D-FRONT dataset [Fu et al. 2021], which contains 18,968 diversely furnished rooms in 6,813 irregularly shaped houses/scenes. These different types of rooms (e.g., bedrooms, living rooms, dining rooms, and study rooms) are diversely furnished with varying numbers of furniture objects in meaningful locations. This differs from prior methods that use empty shoebox-shaped rooms [Grondin et al. 2020; Ko et al. 2017], because room shapes and the existence of furniture will significantly modify the acoustic signature of the room, including shifting the room modes in the low frequency. 3D-FRONT dataset is designed to have realistic scene layouts, and has received higher human ratings in subjective studies [Fu et al. 2021]. Generating audio data from these models allows us to better approximate real-world acoustics.

2.2 Semantic Acoustic Material Assignment

Because the 3D-FRONT dataset also provides object semantics (i.e., object material labels), it is possible to assign more meaningful acoustic materials to individual surfaces or objects in the scene. For example, an object with “window” description is likely to be matched with several types of window glass material from the acoustic material database. SoundSpaces dataset [Chen et al. 2020]
also utilizes scene labels by using empirical manual material assignment (e.g., acoustic materials of carpet, gypsum board, and acoustic tile are assumed for floor, wall, and ceiling classes), creating a one-to-one visual-acoustic material mapping for the entire dataset. This approach works for a small set of known material types. Instead, we present a general and fully automatic method that works for unknown materials with unstructured text descriptions.

To start with, we retrieve measured frequency-dependent acoustic absorption coefficients for 2, 042 unique materials from a room acoustic database [Kling 2018]. The descriptions of these materials do not directly match the semantic labels of objects in the 3D-FRONT dataset. Therefore, we present a method to calculate the semantic similarity between each label and material description using natural language processing (NLP) techniques. In NLP research, sentences can be encoded into fixed length numeric vectors known as sentence embedding [Mishra and Viradiya 2019]. One goal of sentence embedding is to find semantic similarities to identify text with similar meanings. Transformer networks have been very successful in generating good sentence embeddings [Liu et al. 2020] such that sentences with similar meanings will be relatively close in the embedding vector space. We leverage a state-of-the-art sentence transformer model 1 [Reimers and Gurevych 2019] that calculates an embedding of dimension 512 for each sentence. Our assignment process is described in Algorithm 1.

**Algorithm 1: Semantic material assignment**

**Input:** Object name string \( s_0 \)

**Data:** Embedding model \( f : s \mapsto \mathbb{R}^{512} \);

Acoustic material names \( \{m_1, m_2, \ldots, m_N\} \)

**Output:** Acoustic material assignment

\[
e_0 \leftarrow f(s_0); \quad \text{// embedding for object name}
\]

for \( i \leftarrow 1 \) to \( N \) do

\[
e_i \leftarrow f(m_i); \quad \text{// embedding for acoustic material}
\]

\[
w_i \leftarrow \max(0, \cosineSimilarity(e_0, e_i));
\]

end

 Assign \( m_i \) with probability \( P(X = m_i) = w_i / \sum_{j=1}^{N} w_j \);  

The key idea of our assignment is to use the cosine similarity (truncated to be non-negative) between the embedding vectors of the input and target material names as sampling weights to assign materials. Note that we do not directly pick the material with the highest score because for the same type of material, there are still different versions with different absorption coefficients (e.g., in terms of thickness, brand, painting). These slightly different descriptions of the same material are likely to have similar semantic distance to the 3D-FRONT material label being considered. Therefore, we use a probabilistic assignment to increase the diversity of our materials.

### 2.3 Geometric-Wave Hybrid Simulation

It is well known that geometric acoustic (GA) methods do not model low-frequency acoustic effects well due to the linear ray assumption [Funkhouser et al. 1998; Schissler et al. 2014]. Therefore, we use a hybrid propagation algorithm that combines wave-based methods with GA. These wave-based methods can accurately model low-frequency wave effects, but their running time increases as the third or fourth power of the highest simulation frequency [Raghuvanshi et al. 2009]. Given the high time complexity of wave-based methods, we also want to use methods that are: (1) highly parallelizable so that dataset creation takes acceptable time on high-performance computing clusters; (2) compatible with arbitrary geometric mesh representations and acoustic material inputs; and (3) open-source so that the simulation pipeline can be reused by the research community. In this paper, we develop our hybrid simulation pipeline from a CPU-based GA software pgysound 2 and a GPU-based wave FDTD software PFFDTD [Hamilton 2021].

#### 2.3.1 Inputs

The scene CAD models from the 3D-FRONT dataset, each corresponding to several rooms with open doors, are represented in a triangle mesh format. Most GA methods have native support for 3D mesh input. The meshes are converted to voxels to be used as geometry input to the wave-based solver. We sample source and receiver locations in each scene by grid sampling in all three dimensions with 1m spacing. This sampling yields from tens to thousands source and receiver pairs in each scene depending on its size. We perform collision checking to ensure all sampled locations have at least 0.2m clearance to any object in the scene.

We assign acoustic absorption coefficients according to the scheme presented in § 2.2. These coefficients can be directly used by the GA method and integrated with the passive boundary impedance model used by the wave FDTD method [Bilbao et al. 2015]. The GA method also requires scattering coefficients, which account for the energy ratio between specular and diffuse reflections. Such data is less conventionally measured and is not available from the material database in § 2.2. It is known that scattering coefficients tend to be negligible (e.g., \( \leq 0.05 \)) for low-frequency bands [Cox et al. 2006] handled by the wave method. Therefore, we sample scattering coefficients by fitting a normal distribution to 37 sets of frequency-dependent scattering coefficients obtained from the benchmark data in § 3.1, which are only used by the GA method.

#### 2.3.2 Setup

For the GA method, we set 20,000 rays and 200 maximum depth for specular and diffuse reflections. The GA simulation is intended for human aural range, while most absorption coefficient data is only valid for octave bands from 63Hz to 8,000Hz. The ray-tracing stops when the maximum depth is reached or the energy is below the hearing threshold.

For the wave-based FDTD method, we set the maximum simulation frequency to 1,400Hz. The grid spacing is set according to 10.5 points per wavelength. Our simulation duration is 1.5s, which is sufficient to capture most indoor reverberation times and can be extended to generate additional data.

#### 2.3.3 Automatic Calibration

Before combining simulated IRs from two methods, one important step is to properly calibrate their relative energies. Southern et al. [2011] describe two objective calibration methods: (1) pre-defining a crossover frequency range near the highest frequency of the wave method and aligning the sound level of the two methods in that range; (2) calibrating the peak level from time-windowed, bandwidth-matched regions in the wave and the GA methods. Both calibration methods are used

1. https://huggingface.co/sentence-transformers/distiluse-base-multilingual-cased-v2
2. https://github.com/GAMMA-UMD/pgysound
case-by-case for each pair of IRs. However, the first method is not physically correct, and the second method can be vulnerable when the direct sound is not known, as with occluded direct rays in the GA method. Southern et al. [2013] improved the second method by calculating calibration parameters once in free-field condition using a band-limited source signal.

We use a similar calibration procedure. The calibration source and receivers have a fixed distance \( r = 1\, \text{m} \) in a large volume with absorbing boundary conditions, and the 90 calibration receivers span a 90° arc to account for the influence of propagation direction along FDTD grids. The source impulse signal is low-pass filtered at a cut-off frequency of 255Hz. Since the source signal is a unit impulse, the filtered signal is essentially the coefficients of the low-pass filter. The simulated band-limited IRs are truncated at twice the cut-off frequency of 90 Hz. Since the source signal is a unit impulse, the filtered signal is essentially the coefficients of the low-pass filter. The simulated band-limited IRs are truncated at twice the cut-off frequency of 90 Hz.

The calibration parameter for wave-based FDTD is computed as \( \eta_w = \sqrt{E_s/E_r} \), where \( E_s \) is the total energy of the band-limited point source, and \( E_r \) is the total energy at the receiver point. For multiple receiver points, \( \eta_w \) takes the average value. During wave-based FDTD calibration, each received signal is multiplied by \( \eta_w \), and we can calculate the difference between the calibrated signal and the band-limited source signal. As a result, we obtain a very low mean error of 0.50dB and a max error of 0.85dB among all calibration receivers.

For the GA method, we follow the same procedure though the process is simpler since the direct sound energy is implicit in most GA algorithms (i.e., \( \eta \) scaled by some constant). Another calibration parameter \( \eta_g \) is similarly obtained for the GA method. This calibration process ensures that the full-band transmitted energy from both methods will be \( E = 1 \) at a distance of 1m from a sound source, although the absolute energy does not matter and the two parameters can be combined into one (i.e., only use \( \eta_w' = \eta_w/\eta_g \) for wave calibration). Figure 2 shows an example of simulation results with and without calibration. Without properly calibrating the energies, there will be abrupt sound level changes in the frequency domain, which can create unnatural sound.

For the GA method, we follow the same procedure though the process is simpler since the direct sound energy is implicit in most GA algorithms (i.e., \( \eta \) scaled by some constant). Another calibration parameter \( \eta_g \) is similarly obtained for the GA method. This calibration process ensures that the full-band transmitted energy from both methods will be \( E = 1 \) at a distance of 1m from a sound source, although the absolute energy does not matter and the two parameters can be combined into one (i.e., only use \( \eta_w' = \eta_w/\eta_g \) for wave calibration). Figure 2 shows an example of simulation results with and without calibration. Without properly calibrating the energies, there will be abrupt sound level changes in the frequency domain, which can create unnatural sound.

2.3.4 Hybrid Combination. Ideally we would want to use the wave-based method for the highest possible simulation frequency. Besides the running time, one issue with FDTD scheme is the rising dispersion error with the frequency [Lehtinen 2003]. As a remedy, the FDTD results are first high-pass filtered at a very low frequency (e.g., 10Hz) to remove some DC offset and then low-pass filtered at the crossover frequency to be combined with GA results. We use a Linkwitz-Riley crossover filter [Linkwitz 1976] to avoid ringing artifacts near the crossover frequency, harnessing its use of cascading Butterworth filters. The crossover frequency in this work is chosen to be 1,400Hz to fully utilize the accuracy of wave simulation results. Higher simulation crossover frequencies could be used at the cost of increased FDTD simulation time.

2.4 Analysis and Statistics

Runtime. The runtime of our hybrid simulator depends on specific computational hardware. We utilize a high-performance computing cluster with 20 Intel Ivy Bridge E5-2680v2 CPUs and 2 Nvidia Tesla K20m GPUs on each node. On a single node, our simulator requires about 4,000 computing hours for the wave-based FDTD method and about 2,000 computing hours for the GA method to generate all data.

Distributions. More than 5,000 scene/house models are used. On average, each scene uses 22.5 different acoustic materials. We assign 1,955 unique acoustic materials (out of 2,042) from the material database, and the most frequently used materials are several versions of brick, concrete, glass, wood, and plaster. The occurrence of most frequently used materials are visualized in Figure 3.

The distribution of distances between all source and receiver pairs are visualized in Figure 4. We also show the relationship between the volume of each 3D house model and the reverberation time for that model in Figure 5 to highlight the wide distribution of our dataset. Overall, we have a balanced distribution of the reverberation times in the normal range.
We evaluate the benefits of generating a diverse and high-quality IR datasets are designed as diffraction benchmarks and we use them to evaluate the performance of our hybrid simulator, especially at lower frequencies.

The 3D models of the reference scenes along with frequency-dependent acoustic absorption and scattering coefficients are directly used for our hybrid simulator. We use these three scenes because they are considered difficult for the geometric method alone [Brinkmann et al. 2019].

3.2 Results
We use the room geometry, source-listener locations, and material definitions as an input to our simulation pipeline. Note that the benchmark only provide absorption and scattering coefficients, and no impedance data is directly available for wave solvers. Thus, we only use fitted values rather than exact values. The IRs generated by the GA method and our hybrid method and the measured IRs from the benchmark are compared in the frequency domain in Figure 6. In these scenes, the source and receiver are placed on different sides of the obstacle and the semi-anechoic room only has floor reflections. In the high frequency range, there are fewer variations in the measured response, and both methods capture the general trend of energy decay despite response levels not being perfectly matched. This demonstrates that our hybrid sound simulation pipeline is able to generate more accurate results than the GA method for complex real-world scenes.

4 APPLICATIONS
We use our dataset on three speech processing applications that use deep learning methods. Synthetic IRs have been widely used for training neural networks for automatic speech recognition, speech enhancement, and source separation (as described in § 1). We evaluate the benefits of generating a diverse and high-quality IRs dataset over prior methods used to generate synthetic IRs.

In general, these speech tasks use IR datasets to augment anechoic speech data to create synthetic distant training data, whereas the test data is reverberant data recorded in the real world. When high-quality IR datasets are used, the training set is expected to generalize better on the test data. We simulate distant speech data \( x_d[t] \) by convolving anechoic speech \( x_c[t] \) with different IRs \( r[t] \) and adding environmental noise \( n[t] \) from BUT ReverbDB [Szöke et al. 2019] dataset using

\[
    x_d[t] = x_c[t] \ast r[t] + n[t+\ell].
\]

Then the data is used by different training procedure and neural network architectures on respective benchmarks. In the following tests, we also examine variations of our datasets: GA (geometric method only), FDTD (only up to 1,400Hz), and GWA (hybrid method).

4.1 Automated Speech Recognition
Automatic speech recognition (ASR) aims to convert speech data to text transcriptions. The performance of ASR models is measured by the word error rate (WER), which is the percentage of incorrectly transcribed words in the test data. The AMI speech corpus [Carletta et al. 2005] consisting of 100 hours of meeting recording is used as our benchmark. And we use the Kaldi toolkit [Povey et al. 2011] to run experiments on this benchmark. We randomly select 30,000
Figure 6: Frequency responses of geometric and hybrid simulations compared with measured IRs in BRAS benchmarks RS5-7 [Aspöck et al. 2020]. Images of each setup are attached in the corners of the graph. We notice that the IRs generated using our hybrid method closely match with the measured IRs, as compared to those generated using GA methods. This demonstrates the higher quality and accuracy of our IRs as compared to the ones generated by prior GA methods highlighted in Table 1.

IRs out of 2M synthetic IRs in GWA to augment the anechoic training set in AMI, and report the WER on the real-world test set. A lower WER indicates that the synthetic distant speech data used for training is closer to real-world distant speech data. We highlight the improved accuracy obtained using GWA over prior synthetic IR generators in Table 2.

In this benchmark, we include more comparisons with prior datasets from Table 1 and we also incorporate SoundSpaces [Chen et al. 2018] data into our pipeline. We have replaced the original manual material assignment in SoundSpaces with our semantic assignment (SoundSpaces-semantic), and observe a 0.9% WER improvement. To study the effect of model diversity, we use a subset of house models from 3D-FRONT (GWA subset) that has the same number (103) of scenes as SoundSpaces, this results in a 0.8% degradation in WER compared with our full dataset. Overall, we see that our GWA dataset outperforms prior synthetic datasets, where BIRD+Ko et al. [2017] uses an image-method simulator in shoebox-shaped rooms and SoundSpaces uses a ray-tracing based simulator, and has the closest WER to that of the real-world BUT Reverb [Szöke et al. 2019] dataset, due to both the inclusion of more diverse 3D scenes and our semantic material assignment.

### 4.2 Speech Dereverberation

Speech dereverberation aims at converting a reverberant speech signal back to its anechoic version to enhance its intelligibility. For our tests, we use SkipConvNet [Kothapally et al. 2020], a U-Net based speech dereverberation model. The model is trained on the 100-hour subset of Librispeech dataset [Panayotov et al. 2015]. The reverberant input to the model is generated by convolving the clean Librispeech data with our synthetically generated IRs. We test the performance of the model on real-world recordings from the VOiCES dataset [Richey et al. 2018] which contain reverberant Librispeech data. We report the speech-to-reverberation modulation energy ratio (SRMR) [Falk et al. 2010] over the test set. A higher value of SRMR indicates lower reverberation and higher speech quality. As seen from Table 3, our proposed dataset obtains better dereverberation performance as compared to all other datasets.

### Table 2: Far-field ASR results obtained for the AMI corpus.

| IR used                              | WER [%] |
|--------------------------------------|---------|
| None (anechoic)                      | 64.2    |
| BIRD [Grondin et al. 2020]+Ko et al. [2017] | 48.4    |
| BUT Reverb [Szöke et al. 2019]       | 46.6    |
| SoundSpaces (manual) [Chen et al. 2020] | 51.2    |
| SoundSpaces-semantic                 | 50.3    |

| GWA (ours)                           | 8.14     |
4.3 Speech Separation

We train a model to separate reverberant mixtures of two speech signals into its constituent reverberant sources. We use the Asteroid [Pariente et al. 2020] implementation of the DPRNN-TasNet model [Luo et al. 2020] for our benchmarks. The 100-hour split of the Libri2Mix [Cosenino et al. 2020] dataset is used for training. We test the model on reverberant mixtures generated from the VOiCES dataset. We report the improvement in scale-invariant signal-to-distortion ratio (SI-SDRi) [Le Roux et al. 2019] to measure separation performance. Higher SI-SDRi implies better separation. As seen from Table 4, our GWA outperforms alternative approaches.

Table 4: SI-SDRi values reported for different IR generation methods. We report results separately for the four rooms used to capture the test set (higher is better).

| IR used    | Room 1 | Room 2 | Room 3 | Room 4 |
|------------|--------|--------|--------|--------|
| SoundSpaces | 1.83   | 1.74   | 1.02   | 1.80   |
| GA         | 2.25   | 2.55   | 1.44   | 2.55   |
| FDTD       | 2.36   | 2.43   | 1.33   | 2.46   |
| GWA (ours) | 2.94   | 2.76   | 1.86   | 2.91   |

5 CONCLUSION AND FUTURE WORK

We introduced a large new audio dataset of synthetic room impulse responses and the simulation pipeline, which can take different scene configurations and generate higher quality IRs. We demonstrated the improved accuracy of our hybrid geometric-wave simulator on three difficult scenes from the BRAS benchmark. As compared to prior datasets, GWA has more scene diversity than recorded datasets, and has more physically accurate IRs than other synthetic datasets. We also use our dataset with audio deep learning to improve the performance of speech processing applications.

Our dataset only consists of synthetic scenes, and may not be as accurate as real-world captured IRs. In many applications, it is also important to model ambient noise. In the future, we will continue growing the dataset by including more 3D scenes to further expand the acoustic diversity of the dataset. We plan to evaluate the performance of other audio deep learning applications.

ACKNOWLEDGMENTS

The authors acknowledge the University of Maryland supercomputing resources (http://hpc.umd.edu) made available for conducting the research reported in this paper and UMIACS for providing additional computing and storage resources. The authors also thank Dr. Brian Hamilton for answering questions about the PFFDFT software. This work is supported in part by ARO grants W911NF-18-1-0313, W911NF-21-1-0026, NSF grant #1910940 and Intel.
