**Abstract**

The combination of antibiotics is one of the strategies to combat drug-resistant bacteria, though only a handful of such combinations are in use, such as the β-lactam combinations. In the present study, the efficacy of a specific sub-inhibitory concentration of cefsulodin with other β-lactams was evaluated against a range of Gram-negative clinical isolates. This approach increased the sensitivity of the isolates, regardless of the β-lactamase production. The preferred target and mechanism of action of cefsulodin were identified in laboratory strains of *Escherichia coli*, by examining the effects of deleting the penicillin-binding protein (PBP) 1a and 1b encoding genes individually. Deletion of PBP1b was involved in sensitizing the bacteria to β-lactam agents, irrespective of its O-antigen status. Moreover, the use of a sub-inhibitory concentration of cefsulodin in combination with a β-lactam exerted an effect similar to that one obtained for PBP1b gene deletion. We conclude that the identified β-lactam/cefsulodin combination works by inhibiting PBP1b (at least partially) despite the involvement of β-lactamases, and therefore could be extended to a broad range of Gram-negative pathogens.

**Introduction**

The use of antibiotics in optimum concentration is among the most desirable criteria for any treatment strategy [1]. Reports suggest that the usage of cefsulodin, a third-generation cephalosporin, in combination with other β-lactam antibiotics, such as cefazolin and cepuroxime, produces a synergistic effect on sensitivity alteration [2]. However, the optimal concentration of cefsulodin is not known and therefore, narrowing down the concentration will facilitate treatment with comparatively lower doses of antibiotics.

Cefsulodin is thought to target penicillin-binding proteins (PBPs) 1a (encoded by *mrcA*) and 1b (encoded by *mrcB*), which are bifunctional enzymes with transglycosylase and transpeptidase activity [3]; but, it is not known which one of the two PBPs is the preferred target. Reports [4,5] claim that PBP1b deletion alters β-lactam sensitivity; however, the reversal of sensitivity by PBP1b complementation has not been established. In addition, much of the work in this area has been conducted on *E. coli* K-12 laboratory strains devoid of O-antigens. As O-antigen plays a significant role in β-lactam sensitization [6], it is important to study its effect in the context of PBP1b deletion.

Some β-lactams that target a specific PBP produce an effect similar to the deletion of that PBP, for e.g. inactivation of PBP1 by cefsulodin [5,7]. Here, we report a combination of cefsulodin with other β-lactams that acts synergistically in sensitizing laboratory and clinical isolates, regardless of the presence of β-lactamases and/or O-antigens.

**Materials and Methods**

The clinical isolates used for the study were collected from the Tropical School of Medicine, Kolkata, India. These isolates were identified using a combination of biochemical tests and 16S ribosomal DNA sequencing. The obtained sequences were matched with the sequences in the database (National Center for Biotechnology Information), and sequences with a more than 98% match were taken into consideration (as there were no new sequence results, they have not been deposited into Genebank). Primarily, the strains were screened for the presence of β-lactamase by assessing the ability of the cell lysates to hydrolyze nitrocefin [8], and thereafter, specifically for CTX-M β-lactamases (most widespread extended-spectrum β-lactamase) by using polymerase chain reaction with specific primer pairs [9]. The minimum inhibitory concentration (MIC) values of the antibiotics from both penicillin and cephalosporin groups were determined according to CLSI guidelines either individually or in combination [6,7,10]. Bacterial strains used for genetic manipulations were derived from the *E. coli* K-12 strains, CS109 (O-antigen negative strain) and 2443 (O-antigen positive strain). The PBP genes *mrcA* and *mrcB* were deleted by P1 transductions followed by the excision of the *res-npt-res* cassette by transient expression of the RP4 ParA resolvase [7,11,12]. Strains and plasmids used in this study are listed in Table 1.

PBP deletion was confirmed by labeling the cells with Bocillin FL (Invitrogen Inc., Carlsbad, CA, USA) and visualizing the PBPs separated in SDS-PAGE [13]. The PBP1a and 1b clones (pFS1A1 and pSAD588-1, respectively) were gifted by Professor Kevin D. Young. MIC values were determined for *E. coli* CS109, 2443 and
their deletion mutants, before and after complementation. To check the $\beta$-lactam binding efficacy of PBP1a and 1b, competition assays between cefsulodin and Bocillin FL were performed, using mrcA and mrcB deleted strains [8]. The killing kinetics was evaluated following the methods described earlier [14].

**Results and Discussion**

**Sub-inhibitory Concentration of Cefsulodin Combination Sensitizes Gram-negative Clinical Isolates**

Clinical isolates selected for this study were identified as the members of *Enterobacteriaceae* group. The strains Tr1 (*Salmonella enterica*), Tr5 (*Shigella* sp.), Tr10 (*Klebsiella pneumoniae*), Tr7 (*Escherichia coli*), NGM2 (*Escherichia coli*), NGM3 (*Escherichia coli*) and the type strain NCIM 2300 (*Proteus mirabilis*) showed significant $\beta$-lactamase activity while the strains Tr2 (*Vibrio cholera*), NGM6 (*Escherichia coli*), and the type strain NCIM 2397 (*Serratia marcescens*) lacked $\beta$-lactamase activity (Figure 1). Susceptibilities of these strains to various $\beta$-lactams were tested and the MICs varied from 2 mg/L to 500 mg/L (Table 2). When combined with cefsulodin, at concentrations ranging from 2 mg/L to 8 mg/L, susceptibilities of all the strains were enhanced. However, differences in susceptibilities were negligible when cefsulodin was used at concentrations higher than 4 mg/L. The combination successfully sensitized the strains 2 to 32 fold compared to their original MIC values (Table 2). Therefore, the combination of cefsulodin at a sub-inhibitory level (4 mg/L) with other $\beta$-lactam agents was effective against both $\beta$-lactamase negative and positive strains. For further experiments, the concentration of cefsulodin used in the combination was 4 mg/L.

**O-antigen does not Impact Patterns of Antibiotic Sensitivity in PBP Mutants**

It is not known whether the preferred target of cefsulodin is PBP1a or PBP1b, so mrcA and mrcB genes were deleted separately from *E. coli* K12 strains that either lacked or contained O-antigen (CS109 and 2443, respectively). PBP loss was confirmed by Bocillin FL labeling (Figure 2). The effect of O-antigens on $\beta$-

Figure 1. $\beta$-lactamase assay for various strains used in this study. $\beta$-lactamase activity could not be detected for Tr2, NGM6 and *Serratia marcescens*. doi:10.1371/journal.pone.0048598.g001
lactam sensitivity of the PBP mutants was tested and the patterns of alteration in β-lactam sensitivity were found identical for the strains, regardless of the presence of O-antigens (Table 3). The only difference was that the strains derived from Escherichia coli 2443 were comparatively 2 to 4 times more sensitive to the penicillin group of antibiotics [6]. As the lactam sensitivity in both strains. However, no change in β-lactam sensitivity was observed for either of the PBP1a mutants indicating that the intact PBP1b protein present in the ΔmrcA mutants is able to compensate functionally for the PBP1a deletion (Table 3).

Deletion of PBP1a is Unable to Sensitize E. coli Cells to β-lactams

It is believed that PBP1a and 1b compensate each other functionally for transglycosylase and transpeptidase activity; thus, in the absence of PBP1a, PBP1b can compensate its function and vice versa [11]. Therefore, to check the effect of PBP1b deletion on the sensitivity of β-lactam antibiotics, we used the CS109ΔmrcB and 2443ΔmrcB strains. These strains were sensitive to the representative antibiotics of various generations of cephalosporins, with the change in sensitivity level ranging from 16 to 32 fold, as compared to their respective parent strains (Table 3). The results indicate that in the absence of PBP1b, the intact PBP1a protein may not possess sufficient activity to compensate the physiological functions of PBP1b [15,16]. Next, to check whether PBP1a deletion has a similar role in altering β-lactam sensitivity, the MIC values were determined for CS109Δmrc and 2443ΔmrcA. However, no change in β-lactam sensitivity was observed for either of the PBP1a mutants indicating that the intact PBP1b protein present in the ΔmrcA mutants is able to compensate functionally for the PBP1a deletion (Table 3).

Expression of PBP1b in Trans Restores the Lost β-lactam Resistance

From our results, we inferred a possible involvement of PBP1b in altering β-lactam sensitivity. To strengthen this hypothesis, we checked whether the expression of PBP1b in trans could reverse the augmented β-lactam sensitivity in CS109ΔmrcB and 2443ΔmrcB (Table 3). Expression of mrcB gene from plasmid pSAD588-1 (Table 1) reversed the lost β-lactam sensitivity in both the strains. However, no change in β-lactam sensitivity was observed upon expressing mrcA (from plasmid pFS1A1) in 2443ΔmrcA. Therefore, the results obtained from both the deletion and complementation experiments demonstrate that PBP1b is involved in maintaining an intrinsic β-lactam resistance, especially to cephalosporins.

Cefosulodin Binding Efficacy of PBP1a is Ten Times Higher than that of PBP1b

To understand the biochemical origins of the variation in the physiological functions of PBP1a and PBP1b, their binding efficacy for cefosulodin was determined through a competition assay between cefosulodin and Bocillin FL using the strains 2443ΔmrcA and 2443ΔmrcB. The relative efficacy of binding of cefosulodin to PBP1s was determined through their ability to inhibit the binding of Bocillin FL by 50%, also known as IC50 value (50% inhibitory concentration). Cefosulodin was found to interact specifically with PBP 1a and 1b. The band intensity of 2443/pSAD588-1 induced by 0.05%, 0.1% and 0.2% arabinose respectively; Lane 6: 2443ΔmrcA.

Assessment of the IC50 of cefsulodin for the PBP1s revealed that PBP1a has an IC50 value that is approximately 10 times lower than that of PBP1b. This result is in agreement with the observations reported by Ramachandran et al [17].

**Sub-inhibitory Levels of Cefsulodin in Combination with β-lactams Mimics PBP1b Deletion.**

The efficiency of sub-inhibitory concentrations of cefsulodin in combination with other β-lactams was tested. As described above, 4 mg/L of cefsulodin was most effective in sensitizing the clinical isolates to β-lactams. The MIC values obtained for each antibiotic tested in combination with cefsulodin (4 mg/L) resembled the pattern observed with mrcB deletion. However, the enhancements in sensitivity were in a range from 2 to 10 fold for the entire set of antibiotics tested (Table 4).

To check the effect of 4 mg/L cefsulodin in combination with other β-lactams, we evaluated the killing rate of parent and PBP1b mutant strains using 1× and 2× MICs of ampicillin and cefotaxime as representatives of penicillin and cephalosporin groups, respectively. The results were plotted as log cfu/mL versus time [14] (Figure 3). Interestingly, the killing rate of 2443ΔmrcB in the absence of cefsulodin was similar to that of the 2443 parent strain in presence of 4 mg/L cefsulodin. Therefore, β-lactam in combination with 4 mg/L cefsulodin showed an effect similar to PBP1b loss in *E. coli*.

Overall, based on the obtained results, it can be speculated that in a cell where both the PBPs are intact, cefsulodin inhibits PBP1a at a concentration 10 times lower than PBP1b. If concentration of cefsulodin is sub-optimal, majority of PBP1b remain viable for its enzymatic functions. Similar situation prevails for PBP1b deletion mutants leading to unaltered MIC values. However, if the sub-inhibitory dose of cefsulodin is sufficient to inhibit PBP1b (at least partially), the availability of functional PBP1a remains viable for its enzymatic functions. Similar situation prevails for PBP1a deletion mutants leading to unaltered MIC values. However, if the sub-inhibitory dose of cefsulodin is sufficient to inhibit PBP1b (at least partially), the availability of functional PBP1a remains viable for its enzymatic functions. *β*-lactam antibiotics tested

**Conclusion**

It is inferred that PBP1b is involved in altering β-lactam sensitivity, especially for antibiotics of the cephalosporin group. We suggest that by deleting mrcB or its homologs, and/or by applying a sub-inhibitory level of cefsulodin (4 mg/L), the bacterial cells, regardless of the presence of β-lactamases, can be sensitized against conventional β-lactam agents. Further studies in this area may expand our knowledge of combinatorial therapy using cefsulodin as a key component.
