Fast Tracking via Spatio-Temporal Context Learning

Kaihua Zhang, Lei Zhang, Ming-Hsuan Yang, and David Zhang

Abstract

In this paper, we present a simple yet fast and robust algorithm which exploits the spatio-temporal context for visual tracking. Our approach formulates the spatio-temporal relationships between the object of interest and its local context based on a Bayesian framework, which models the statistical correlation between the low-level features (i.e., image intensity and position) from the target and its surrounding regions. The tracking problem is posed by computing a confidence map, and obtaining the best target location by maximizing an object location likelihood function. The Fast Fourier Transform is adopted for fast learning and detection in this work. Implemented in MATLAB without code optimization, the proposed tracker runs at 350 frames per second on an i7 machine. Extensive experimental results show that the proposed algorithm performs favorably against state-of-the-art methods in terms of efficiency, accuracy and robustness.

Index Terms

Object tracking, spatio-temporal context learning, Fast Fourier Transform (FFT).

I. INTRODUCTION

Visual tracking is one of the most active research topics due to its wide range of applications such as motion analysis, activity recognition, surveillance, and human-computer interaction, to name a few [1]. The main challenge for robust visual tracking is to handle large appearance changes of the target object and the background over time due to occlusion, illumination changes, and pose variation. Numerous algorithms have been proposed with focus on effective appearance models, which can be categorized into generative [2]–[13] and discriminative [14]–[19] approaches.

A generative tracking method learns an appearance model to represent the target and search for image regions with best matching scores as the results. While it is critical to construct an effective appearance model in order to handle various challenging factors in tracking, the involved computational complexity is often increased at the same time. Furthermore, generative methods discard useful information surrounding target regions that can be exploited to better separate objects from backgrounds. Discriminative methods treat tracking as a binary classification problem with local search which estimates decision boundary between an object image patch and the background. However, the objective of classification is to predict instance labels which is different from the goal of tracking to estimate object locations [16]. Moreover, while some efficient feature extraction techniques (e.g., integral image [14]–[18] and random projection [18]) have been proposed for visual tracking, there often exist a large number of samples from which features need to be extracted for classification, thereby entailing computationally expensive operations. Generally speaking, both generative and discriminative tracking algorithms make trade-offs between effectiveness and efficiency of an appearance model. Notwithstanding much progress has been made in recent years, it remains a challenging task to develop an efficient and robust tracking algorithm.

Fig. 1: The proposed method handles heavy occlusion well by learning spatio-temporal context information. Note that the region inside the red rectangle is the context region which includes the target and its surrounding background. Left: although the target appearance changes much due to heavy occlusion, the spatial relationship between the object center (denoted by solid yellow circle) and its surrounding locations in the context region (denoted by solid red circles) is almost unchanged. Middle: the learned spatio-temporal context model (the regions inside the blue rectangles have similar values which show the corresponding regions in the left frames have similar spatial relations to the target center.). Right: the learned confidence map.
In visual tracking, a local context consists of a target object and its immediate surrounding background within a determined region (See the regions inside the red rectangles in Figure 1). Therefore, there exists a strong spatio-temporal relationship between the local scenes containing the object in consecutive frames. For instance, the target in Figure 1 undergoes heavy occlusion which makes the object appearance change significantly. However, the local context containing the object does not change much as the overall appearance remains similar and only a small part of the context region is occluded. Thus, the presence of local context in the current frame helps predict the object location in the next frame. This temporally proximal information in consecutive frames is the temporal context which has been recently applied to object detection [20]. Furthermore, the spatial relation between an object and its local context provides specific information about the configuration of a scene (See middle column in Figure 1) which helps discriminate the target from background when its appearance changes much. Recently, several methods [21]–[24] exploit context information to facilitate visual tracking with demonstrated success. However, these approaches require high computational loads for feature extraction in training and tracking phases.

In this paper, we propose a fast and robust tracking algorithm which exploits spatio-temporal local context information. Figure 2 illustrates the basic flow of our algorithm. First, we learn a spatial context model between the target object and its local surrounding background based on their spatial correlations in a scene by solving a deconvolution problem. Next, the learned spatial context model is used to update a spatio-temporal context model for the next frame. Tracking in the next frame is formulated by computing a confidence map as a convolution
II. Problem Formulation

The tracking problem is formulated by computing a confidence map which estimates the object location likelihood:

$$c(x) = P(x|o),$$

where $x \in \mathbb{R}^2$ is an object location and $o$ denotes the object present in the scene. In the following, the spatial context information is used to estimate (17) and Figure 3 shows its graphical model representation.

In the current frame, we have the object location $x^*$ (i.e., coordinate of the tracked object center). The context feature set is defined as $X^C = \{ c(z) = (I(z), z) | z \in \Omega_c(x^*) \}$ where $I(z)$ denotes image intensity at location $z$ and $\Omega_c(x^*)$ is the neighborhood of location $x^*$. By marginalizing the joint probability $P(x|c(z)|o)$, the object location likelihood function in (17) can be computed by

$$c(x) = P(x|o)$$
$$= \sum_{c(z)\in X^C} P(x,c(z)|o)$$

$$= \sum_{c(z)\in X^C} P(x|c(z),o)P(c(z)|o),$$

where the conditional probability $P(x|c(z),o)$ models the spatial relationship between the object location and its context information which helps resolve ambiguities when the image measurements allow different interpretations, and $P(c(z)|o)$ is a context prior probability which models appearance of the local context. The main task in this work is to learn $P(x|c(z),o)$ as it bridges the gap between object location and its spatial context.
A. Spatial Context Model

The conditional probability function $P(x|c(z), o)$ in (2) is defined as

$$P(x|c(z), o) = h^{sc}(x - z),$$

(3)

where $h^{sc}(x - z)$ is a function (See Section II-D) with respect to the relative distance and direction between object location $x$ and its local context location $z$, thereby encoding the spatial relationship between an object and its spatial context.

Note that $h^{sc}(x - z)$ is not a radially symmetric function (i.e., $h^{sc}(x - z) \neq h^{sc}(|x - z|)$), and takes into account different spatial relationships between an object and its local contexts, thereby helping resolve ambiguities when similar objects appear in close proximity. For example, when a method tracks an eye based only on appearance (denoted by $z_l$) in the davidindoor sequence shown in Figure 3, the tracker may be easily distracted to the right one (denoted by $z_r$) because both eyes and their surrounding backgrounds have similar appearances (when the object moves fast and the search region is large). However, in the proposed method, while the locations of both eyes are at similar distances to location $x^*$ (here, it is location of the context relative to object location $z_l$), their relative locations to $x^*$ are different, thereby resulting in different spatial relationships, i.e., $h^{sc}(z_l - x^*) \neq h^{sc}(z_r - x^*)$.

That is, the non-radially symmetric function $h^{sc}$ helps resolve ambiguities effectively.

B. Context Prior Model

In (2), the context prior probability is simply modeled by

$$P(c(z)|o) = I(z)w_{\sigma}(z - x^*),$$

(4)

where $I(\cdot)$ is image intensity that represents appearance of context and $w_{\sigma}(\cdot)$ is a weighted function defined by

$$w_{\sigma}(z) = ae^{-\frac{a^2}{\sigma^2}},$$

(5)

where $a$ is a normalization constant that restricts $P(c(z)|o)$ in (4) to range from 0 to 1 that satisfies the definition of probability and $\sigma$ is a scale parameter.

In (4), it models focus of attention that is motivated by the biological visual system which concentrates on certain image regions requiring detailed analysis [25]. The closer the context location $z$ is to the currently tracked target location $x^*$, the more important it is to predict the object location in the coming frame, and larger weight should be set. Different from our algorithm that uses a spatially weighted function to indicate the importance of context at different locations, there exist other methods [26], [27] in which spatial sampling techniques are used to focus more detailed contexts at the locations near the object center (i.e., the closer the location is to the object center, the more context locations are sampled).

C. Confidence Map

The confidence map of an object location is modeled as

$$c(x) = P(x|o) = be^{-\left|\frac{x - x^*}{\alpha}\right|^\beta},$$

(6)
where $b$ is a normalization constant, $\alpha$ is a scale parameter and $\beta$ is a shape parameter (See Figure 4).

The object location ambiguity problem often occurs in visual tracking which adversely affects tracking performance. In [17], a multiple instance learning technique is adopted to handle the location ambiguity problem with favorable tracking results. The closer the location is to the currently tracked position, the larger probability that the ambiguity occurs with (e.g., predicted object locations that differ by a few pixels are all plausible solutions and thereby cause ambiguities). In our method, we resolve the location ambiguity problem by choosing a proper shape parameter $\beta$. As illustrated in Figure 4, a large $\beta$ (e.g., $\beta = 2$) results in an oversmoothing effect for the confidence value at locations near to the object center, thereby failing to effectively reduce location ambiguities. On the other hand, a small $\beta$ (e.g., $\beta = 0.5$) yields a sharp peak near the object center, thereby only activating much fewer positions when learning the spatial context model. This in turn may lead to overfitting in searching for the object location in the coming frame. We find that robust results can be obtained when $\beta = 1$ in our experiments.

D. Fast Learning Spatial Context Model

Based on the confidence map function (6) and the context prior model (4), our objective is to learn the spatial context model (3). Putting (6), (4) and (3) together, we formulate (2) as

$$c(x) = be^{-\frac{|x-x^*|}{\alpha^\beta}}$$

$$= \sum_{z \in \Omega_c(x^*)} h^{sc}(x-z)I(z)w_\sigma(z-x^*)$$

$$= h^{sc}(x) \otimes (I(x)w_\sigma(x-x^*)),$$

where $\otimes$ denotes the convolution operator.

We note (7) can be transformed to the frequency domain in which the Fast Fourier Transform (FFT) algorithm [28] can be used for fast convolution. That is,

$$\mathcal{F}(be^{-\frac{|x-x^*|}{\alpha^\beta}}) = \mathcal{F}(h^{sc}(x)) \odot \mathcal{F}(I(x)w_\sigma(x-x^*)),$$
where $\mathcal{F}$ denotes the FFT function and $\odot$ is the element-wise product. Therefore, we have

$$h_{sc}(x) = \mathcal{F}^{-1}\left( \frac{\mathcal{F}(be^{-\frac{|x-x^*|}{\sigma^2}})}{\mathcal{F}(I(x)w_\sigma(x-x^*))} \right),$$

where $\mathcal{F}^{-1}$ denotes the inverse FFT function.

### III. Proposed Tracking Algorithm

Figure 2 shows the basic flow of our algorithm. The tracking problem is formulated as a detection task. We assume that the target location in the first frame has been initialized manually or by some object detection algorithms. At the $t$-th frame, we learn the spatial context model $h_{sc}^t(x)$ (9), which is used to update the spatio-temporal context model $H_{stc}^{t+1}(x)$ (12) and applied to detect the object location in the $(t+1)$-th frame. When the $(t+1)$-th frame arrives, we crop out the local context region $\Omega_c(x^*_t)$ based on the tracked location $x^*_t$ at the $t$-th frame and construct the corresponding context feature set $X_{c,t+1} \triangleq \{c(z) = (I_{t+1}(z), z) | z \in \Omega_c(x^*_t)\}$. The object location $x^*_{t+1}$ in the $(t+1)$-th frame is determined by maximizing the new confidence map

$$x^*_{t+1} = \arg \max_{x \in \Omega_c(x^*_t)} c_{t+1}(x),$$

where $c_{t+1}(x)$ is represented as

$$c_{t+1}(x) = \mathcal{F}^{-1}\left( \mathcal{F}(H_{stc}^t(x)) \odot \mathcal{F}(I_{t+1}(x)w_\sigma(x-x^*)) \right),$$

which is deduced from (8).

#### A. Update of Spatio-Temporal Context

The spatio-temporal context model is updated by

$$H_{stc}^{t+1} = (1-\rho)H_{stc}^t + \rho h_{sc}^t,$$

where $\rho$ is a learning parameter and $h_{sc}^t$ is the spatial context model computed by (9) at the $t$-th frame. We note (12) is a temporal filtering procedure which can be easily observed in frequency domain

$$H_{stc}^\omega = F_\omega h_{sc}^\omega,$$

where $H_{stc}^\omega \triangleq \int H_{stc}^t e^{-jwt} dt$ is the temporal Fourier transform of $H_{stc}^t$ and similar to $h_{sc}^\omega$. The temporal filter $F_\omega$ is formulated as

$$F_\omega = \frac{\rho}{e^{j\omega} - (1-\rho)},$$

where $j$ denotes imaginary unit. It is easy to validate that $F_\omega$ in (14) is a low-pass filter [28]. Therefore, our spatio-temporal context model is able to effectively filter out image noise introduced by appearance variations, thereby leading to more stable results.
B. Update of Scale

According to (11), the target location in the current frame is found by maximizing the confidence map derived from the weighted context region surrounding the previous target location. However, the scale of the target often changes over time. Therefore, the scale parameter $\sigma$ in the weight function $w_\sigma (5)$ should be updated accordingly. We propose the scale update scheme as

\[
\begin{align*}
    s_t' &= \sqrt{\frac{c_t(x_\star_t)}{c_{t-1}(x_\star_{t-1})}}, \\
    \bar{s}_t &= \frac{1}{n} \sum_{i=1}^{n} s_{t-i}', \\
    s_{t+1} &= (1 - \lambda)s_t + \lambda \bar{s}_t, \\
    \sigma_{t+1} &= s_t \sigma_t,
\end{align*}
\]

where $c_t(\cdot)$ is the confidence map that is computed by (11), and $s_t'$ is the estimated scale between two consecutive frames. To avoid oversensitive adaptation and to reduce noise introduced by estimation error, the estimated target scale $s_{t+1}$ is obtained through filtering in which $\bar{s}_t$ is the average of the estimated scales from $n$ consecutive frames, and $\lambda > 0$ is a fixed filter parameter (similar to $\rho$ in (12)). The derivation details of (15) can be found in the Appendix V.

C. Analysis and Discussion

We note that the low computational complexity is one prime characteristic of the proposed algorithm in which only 6 FFT operations are involved for processing one frame including learning the spatial context model (9) and computing the confidence map (11). The computational complexity for computing each FFT is only $O(MN \log(MN))$ for the local context region of $M \times N$ pixels, thereby resulting in a fast method (350 frames per second in MATLAB on an i7 machine). More importantly, the proposed algorithm achieves robust results as discussed bellow.

**Difference with related work.** It should be noted that the proposed spatio-temporal context tracking algorithm is significantly different from recently proposed context-based methods [21]–[24] and approaches that use FFT for efficient computation [19], [29], [30].

All the above-mentioned context-based methods adopt some strategies to find regions with consistent motion correlations to the object. In [21], a data mining method is used to extract segmented regions surrounding the object as auxiliary objects for collaborative tracking. To find consistent regions, key points surrounding the object are first extracted to help locate the object position [22]–[24]. Next, SIFT or SURF descriptors are used to represent these consistent regions [22]–[24]. Thus, computationally expensive operations are required in representing and finding consistent regions. Moreover, due to the sparsity nature of key points, some consistent regions that are useful for locating the object position may be discarded. In contrast, the proposed algorithm does not have these problems because all the local regions surrounding the object are considered as the potentially consistent regions, and the motion correlations between the objects and its local contexts in consecutive frames are learned by the spatio-temporal context model that is efficiently computed by FFT.
In [29], [30], the formulations are based on correlation filters that are directly obtained by classic signal processing algorithms. At each frame, correlation filters are trained using a large number of samples, and then combined to find the most correlated position in the next frame. In [19], the filters proposed by [29], [30] are kernelized and used to achieve more stable results. The proposed algorithm is significantly different from [19], [29], [30] in several aspects. First, our algorithm models the spatio-temporal relationships between the object and its local contexts which is motivated by the human visual system that uses context to help resolve ambiguities in complex scenes efficiently and effectively. Second, our algorithm focuses on the regions which require detailed analysis, thereby effectively reducing the adverse effects of background clutters and leading to more robust results. Third, our algorithm handles the object location ambiguity problem using the confidence map with a proper prior distribution, thereby achieving more stable and accurate performance for visual tracking. Finally, our algorithm solves the scale adaptation problem but the other FFT-based tracking methods [19], [29], [30] only track objects with a fixed scale and achieve less accurate results than our method.

Robustness to occlusion and distractor. As shown in Figure 1, the proposed algorithm handles heavy occlusion as most of context regions are not occluded which have similar relative spatial relations (See middle column of Figure 1) to the target center, thereby helping determine the target center. Figure 5 illustrates our method is robust to distractor (i.e., the right object). If tracking the target only based on its appearance information, the tracker will be distracted to the right one because of their similar appearances. Although the distractor has similar appearance to the target, most of their surrounding contexts have different appearances (See locations \( z_i, z'_i, i = 1, 2, 4, 5, 7, 8 \)) which are useful to discriminate target from distractor.

IV. EXPERIMENTS

We evaluate the proposed tracking algorithm based on spatio-temporal context (STC) algorithm using 18 video sequences with challenging factors including heavy occlusion, drastic illumination changes, pose and scale variation, non-rigid deformation, background cluster and motion blur. We compare the proposed STC tracker with 18 state-of-the-art methods. The parameters of the proposed algorithm are fixed for all the experiments. For other trackers,
TABLE I: Success rate (SR)(%). Red fonts indicate the best performance while the blue fonts indicate the second best ones. The total number of evaluated frames is 7,591.

B. Experimental Results

We use two evaluation criteria to quantitatively evaluate the 19 trackers: the center location error (CLE) and success rate (SR), both computed based on the manually labeled ground truth results of each frame. The score of success rate is defined as $score = \frac{area(R_t \cap R_g)}{area(R_t \cup R_g)}$, where $R_t$ is a tracked bounding box and $R_g$ is the ground truth bounding box, and the result of one frame is considered as a success if $score > 0.5$. Table I and Table II show the quantitative results in which the proposed STC tracker achieves the best or second best performance in most sequences both in terms of center location error and success rate. Furthermore, the proposed tracker is the most efficient (350 FPS on average) algorithm among all evaluated methods. Although the CST [19] and MOS [30] methods also use FFT for fast computation, the CST method performs time-consuming kernel operations and the MOS tracker computes several correlation filters in each frame, thereby making these two approaches less efficient than the proposed algorithm. Furthermore, both CST and MOS methods only track target with fixed scale, which achieve less accurate results that the proposed method with scale adaptation. Figure 6 shows some tracking results of different trackers. For presentation clarity, we only show the results of the top 7 trackers in terms of average success rates.

Illumination, scale and pose variation. There are large illumination variations in the evaluated sequences. The appearance of the target object in the car4 sequence changes significantly due to the cast shadows and ambient lights (See #200, #250 in the car4 sequence shown in Figure 6). Only the models of the IVT, L1T, Struck and STC methods adapt to these illumination variations well. Likewise, only the VTD and our STC methods perform favorably on the shaking sequence because the object appearance changes drastically due to the stage lights and sudden pose variations. The davidindoort sequence contain gradual pose and scale variations as well as illumination
changes. Note that most reported results using this sequence are only on subsets of the available frames, i.e., not from the very beginning of the davidindoor video when the target face is in nearly complete darkness. In this work, the full sequence is used to better evaluate the performance of all algorithms. Only the proposed algorithm is able to achieve favorable tracking results on this sequence both in terms of accuracy and success rate. This can be attributed to the use of spatio-temporal context information which facilitates filtering out noisy observations (as discussed in Section III-A), thereby enabling the proposed STC algorithm to relocate the target when object appearance changes drastically due to illumination, scale and pose variations.

Occlusion, rotation, and pose variation. The target objects in the woman, girl and bird sequences are partially occluded at times. The object in the girl sequence also undergoes in-plane rotation (See #100, #120 of the girl sequence in Figure 6) which makes the tracking tasks difficult. Only the proposed algorithm is able to track the objects successfully in most frames of this sequence. The woman sequence has non-rigid deformation and heavy occlusion (See #130, #150, #230 of the woman sequence in Figure 6) at the same time. All the other trackers fail to successfully track the object except the Struck and the proposed STC algorithms. As most of the local contexts surrounding the target objects are not occluded in these sequences, such information facilitates the proposed algorithm relocating the object even they are almost fully occluded (as discussed in Figure 1).
Background clutter and abrupt motion. In the animal, cokecan and cliffbar sequences, the target objects undergo fast movements in the cluttered backgrounds. The target object in the chasing sequence undergoes abrupt motion with 360 degree out-of-plane rotation, and the proposed algorithm achieves the best performance both in terms of success rate and center location error. The cokecan video contains a specular object with in-plane rotation and heavy occlusion, which makes this tracking task difficult. Only the Struck and the proposed STC methods are able to successfully track most of the frames. In the cliffbar sequence, the texture in the background is very similar to that of the target object. Most trackers drift to background except the CT, CST, LGT and our methods (See #300 of the cliffbar sequence in Figure 6). Although the target and its local background have very similar texture, their spatial relationships and appearances of local contexts are different which are used by the proposed algorithm when learning a confidence map (as discussed in Section III-C). Hence, the proposed STC algorithm is able to separate the target object from the background based on the spatio-temporal context.

V. CONCLUSION

In this paper, we present a simple yet fast and robust algorithm which exploits spatio-temporal context information for visual tracking. Two local context models (i.e., spatial context and spatio-temporal context models) are proposed which are robust to appearance variations introduced by occlusion, illumination changes, and pose variations. The Fast Fourier Transform algorithm is used in both online learning and detection, thereby resulting in an efficient tracking method that runs at 350 frames per second with MATLAB implementation. Numerous experiments with state-of-the-art algorithms on challenging sequences demonstrate that the proposed algorithm achieves favorable results in terms of accuracy, robustness, and speed.

Appendix

Without loss of generality, we assume the target object is centered at \( x^* = (0, 0) \). Then, the confidence map (i.e., (11)) can be represented as

\[
c(x) = H(x) \otimes (I(x)w_\sigma(x)).
\]  

(16)
Then, we have
\[
c(0, 0) = \int \int_{\Omega_{x,y}} H(x, y) I(-x, -y) w_{\sigma}(x, y) \, dx \, dy. \tag{17}
\]
See Figure 7, when size of the target changes from left to right with ratio \( s \), performing a change of variables \((u, v) = (sx, sy)\), we can reformulate (17)
\[
c_t(0, 0) = \int \int_{\Omega_{x,y}} H_t(x, y) I_t(-x, -y) w_{\sigma_t}(x, y) \, dx \, dy
\]
\[
= \int \int_{\Omega_{x,y}} H_t(u/s, v/s) I_t(-u/s, -v/s) w_{\sigma_t}(u/s, v/s) \frac{1}{s^2} \, du \, dv
\]
\[
= \int \int_{\Omega_{x,y}} H_t(u/s, v/s) I_{t+1}(-u, -v) w_{\sigma_t}(u/s, v/s) \frac{1}{s^2} \, du \, dv
\]
\[
= \int \int_{\Omega_{x,y}} H_t(u/s, v/s) w_{\sigma_t}(-u, -v) I_{t+1}(-u, -v) \frac{1}{s^2} \, du \, dv
\]
\[
\approx \int \int_{\Omega_{x,y}} H_{t+1}(u, v) w_{\sigma_t}(-u, -v) I_{t+1}(-u, -v) \frac{1}{s^2} \, du \, dv
\]
\[
\approx \int \int_{\Omega_{x,y}} H_{t+1}(u, v) w_{\sigma_t}(-u, -v) I_{t+1}(-u, -v) \frac{1}{s^2} \, du \, dv
\]
\[
- \int \int_{\Omega_{x,y} \setminus \Omega_{x_{x,y}}} H_{t+1}(u, v) w_{\sigma_t}(-u, -v) I_{t+1}(-u, -v) \frac{1}{s^2} \, du \, dv
\]
\[
\approx 0 \text{ because } w_{\sigma_t}(-u, -v) \approx 0 \text{ for all } (u,v) \in \Omega_{x,y} \setminus \Omega_{x_{x,y}} \text{ (See Figure 8)}
\]
\[
\approx \int \int_{\Omega_{x,y}} H_{t+1}(u, v) w_{\sigma_t}(-u, -v) I_{t+1}(-u, -v) \frac{1}{s^2} \, du \, dv.
\]
(18)

In (18), we have used the following relationships
\[
H_t(u/s, v/s) \approx H_{t+1}(u, v), \tag{19}
\]
\[
I_t(u/s, v/s) \approx I_{t+1}(u, v). \tag{20}
\]

Because of the proximity between two consecutive frames, as in [2], we can make the above reasonable assumptions which are spatially scaled versions of \( I_t \) and \( H_t \), respectively.

It is difficult to estimate \( s \) from the (18) because of the nonlinearity of the Gaussian weight function \( w_{\sigma_t} \). We adopt an iterative method to approximately obtain \( s \). We utilize the estimated scale \( s_t \) at frame \( t \) to replace the scale
term \( s \) in the Gaussian window \( w_{s \sigma_t} \), and the other scale term that needs to estimate is denoted as \( s_{t+1} \). Thus, (18) is reformulated as

\[
c_t(0, 0) \approx \int \int_{\Omega_{x,y}} H_{t+1}(u, v) w_{s \sigma_t}(-u, -v) I_{t+1}(-u, -v) \frac{1}{s_{t+1}} dvdu
\]

\[
= \int \int_{\Omega_{x,y}} H_{t+1}(u, v) w_{s_{t+1}}(-u, -v) I_{t+1}(-u, -v) \frac{1}{s_{t+1}} dvdu
\]

\[
= \frac{1}{s_{t+1}} c_{t+1}(0, 0),
\]

where we denote

\[
s_{t+1} = s_t \sigma_t.
\]

(22)

Thus, we have

\[
s_{t+1} = \sqrt{\frac{c_{t+1}(0, 0)}{c_t(0, 0)}}
\]

(23)

We average the scales estimated from the former \( n \) consecutive frames to make the current estimation more stable

\[
s_t = \frac{1}{n} \sum_{i=1}^{n} s_{t-i} = \frac{1}{n} \sum_{i=1}^{n} \sqrt{\frac{c_{t-i}(0, 0)}{c_{t-i-1}(0, 0)}}
\]

(24)

To avoid oversensitive scale adaptation, we utilize the follow equation to incrementally update the estimated scale

\[
s_{t+1} = (1 - \lambda)s_t + \lambda s_t.
\]
