Abstract

Background: Ropivacaine hydrochloride (RH) is a local anesthetic and frequently used for perioperative anesthesia and analgesia; but it has potential neurotoxicity, especially when intrathecally used repeatedly for a long time, although the exact mechanism is unclear.

Methods: In this study, the expression of Factor associated suicide receptor (Fas) and its ligand (FasL) in the spinal cord cells was detected in rats receiving repeated intrathecal injection of RH. The paw mechanical withdraw threshold (MWT) was measured before and 3 days after intrathecal cannulation and 24 h after intrathecal administration. Rats received intrathecal injection of 0.5%, 1%, 2% RH at 0.12 ml/kg or saline of equal volume alone. Intrathecal injection was done 8 times with an interval of 1.5h in 12 h. The spinal cord was collected for pathological examination; TUNEL staining was used to assess the apoptosis in the spinal cord and the expression of Fas, FasL, caspase-3, and caspase-8 was detected by qPCR and Western blotting.

Results: 1% and 2% RH groups significantly increased the MWT ($P<0.05$) and more vacuoles or edema was observed in the spinal cord after RH treatment. The apoptosis rates and expression of Fas, FasL, caspase-3, and caspase-8 increased in the RH groups ($P<0.05$).

Conclusions: Repeated intrathecal administration of RH may cause damage to the spinal cord and induce apoptosis in the spinal cord via up-regulating Fas/FasL expression.

1 Background

Ropivacaine hydrochloride (RH), as an amino amide local anesthetic (LA), is often used for perioperative nerve blocks, epidural and spinal anesthesia, and pain management (1). However, some studies have suggested that high dose LAs and long LAs exposure may cause symptoms of nerve injury such as transient neurological syndrome (TNS) and cauda equina syndrome (CES) when they are intrathecally used (2, 3). Most damages are transient and often subclinical, but some complications may induce dyskinesia and sensory disorder (4). These complications are closely related to the neurotoxicity of LAs (5, 6). After nerve injury, the recovery is a long process, and not effective preventive measures have been developed for the nerve injury secondary to repeated intrathecal use of LAs (7).

Currently, the exact mechanism of LAs’ neurotoxicity remains unclear, and multiple signaling pathways have been proposed, of which, apoptosis is a main pathophysiological mechanism (8, 9). The death receptor pathway is a classical form of exogenous apoptosis, and factor associated suicide receptor (Fas) and its ligand (FasL) play an important role in this pathway. Fas, also known as APO-1 / CD95, is a member of the tumor necrosis factor (TNF) receptor family and widely expressed in a variety of cells and tissues. Fas mainly functions to induce apoptosis and immune regulation (10, 11). Fas binding to FasL can activate the Fas-associated death domain (FADD) and procaspase-8, which subsequently activates caspase-3, ultimately leading to apoptosis.
Fas and FasL can be expressed in the nervous system to induce apoptosis in the spinal cord injury (12); Robins-Steele et al. found that intrathecal administration of soluble Fas receptors (sFas) could inhibit the neuronal apoptosis after spinal cord injury (13). Our previous study confirmed that ropivacaine induced Fas/FasL expression in rat pheochromocytoma PC12 cells (14). However, it is unclear whether Fas / FasL is involved in the neurotoxicity of LAs to the spinal cord.

In this study, rats were intrathecally administrated with RH at different concentrations, and the expression of Fas/FasL and caspase related proteins was detected in the spinal cord, aiming to investigate whether the Fas/FasL pathway is involved in the RH-induced neuronal apoptosis in the rat spinal cord.

2 Methods

Animals

Twenty-five healthy male Sprague-Dawley (SD) rats, weighing 200–300 g and aged 6–8 weeks, were purchased from the Experimental Animal Center of the Hubei University of Medicine. The experiment was approved by the Animal Ethics Committee of Xiangyang No.1 People's Hospital. Rats were housed in an environment at 22 ± 2 °C with the relative humidity of 50–60% and 12h:12 h dark-light cycle, and given ad libitum access to food and water. Animals were allowed to accommodate to the environment for 1 week. All procedures performed in studies involving animals were in accordance with the ethical standards of the institution or practice at the Animal Ethics Committee of the Hubei University of Medicine (2018DW003).

Intrathecal catheterization and drug administration

Rats were intraperitoneally anesthetized with 10% chloral hydrate. According to published method (15), a PE-10 catheter (inner diameter, 0.12 mm; outer diameter, 0.35 mm; Smith Medical, UK) was inserted through the L4/L5 intervertebral space(depth: 2 cm) and fixed at the L1-L2 level. The cannulated rats were observed for 3 days. Five rats developing neurological symptoms after cannulation were excluded from this study.

The remaining twenty cannulated rats were randomly divided into 4 groups (n = 5 per group): Saline group, 0.5% RH group, 1% RH group, and 2% RH group. According to the previously reported (16), rats received intrathecal injection of 0.5%, 1%, 2% RH at 0.12 ml/kg (Hengrui, China) or saline of equal volume alone through the catheter. Intrathecal injection was done 8 times with an interval of 1.5 h in 12 h. After the last injection, rats in each group were observed for 24 h.

Behavioral assessment

The mechanical paw withdrawal threshold (MWT) was measured with the Electronic von Frey apparatus (Bioseb, France). In brief rats were placed in a transparent plexiglass box with holes at the bottom to limit the range of motion and animals were allowed to adapt to the environment for 15 min. Then, the von Frey probe was used to directly stimulate the skin of the hind paw of the rat and the pressure increased
gradually. When the rat had behavioral reactions such as raising, licking and screaming, the threshold was recorded as the MWT. All rats were tested at 3-time points: before cannulation, 3 days after cannulation, and 24 h after intrathecal administration. Each rat was tested 3 times with an interval of 15 min. The specific process of the experiment is shown in Fig. 1.

HE staining

Animals were euthanized by CO$_2$ inhalation. The spinal cord tissues were collected at 24 h after the last intrathecal injection. Tissues were embedded in paraffin, then sectioned and stained according to the HE kit instructions (Beyotime, China). The morphology of the spinal cord tissues was observed under a light microscope (Olympus, IX73, Japan), and compared among groups.

TUNEL staining

The apoptosis of spinal cord tissue was detected by TUNEL staining (Roche, Germany) according to the manufacturer’s instructions. After deparaffinization, rehydration, and treatment with 3% H$_2$O$_2$ for 10 min at room temperature, the sections were incubated with proteinase K (1:200 in Tris-buffered saline [TBS]) for 30 min at 37 °C and then treated with Triton-X100 (0.01%) for 20 min. The sections were subsequently incubated with TdT and dUTP-digoxigenin in a humidified chamber at 37 °C for 2 h, followed by three washes in TBS. The sections were subjected to nuclear staining with DAPI and then observed under an inverted fluorescence microscope (Olympus, IX73, Japan). 3 randomly selected fields were selected from the posterior horn in each section. The proportion of TUNEL positive cells was determined at a magnification of 200x.

Quality real-time PCR (qPCR)

Total RNA was extracted using TRIZOL reagents (Invitrogen, USA) from the spinal cord tissues of rats. The RNA extraction was done according to a standard protocol and then the RNA concentration was determined by NanoPhotometry (Implen, Germany). Subsequently, 2 µg of RNA was reverse-transcribed into cDNA according to manufacturer’s instructions (Promega, USA). The qPCR was performed using SYBR Green fluorescent kit, and the reaction was performed in an ABI7500 Real-time PCR system (Applied Biosystems, USA) with a cycle program as follows: denaturation for 2 min at 95 °C, 40 cycles of 95 °C for 15 s, and 60 °C for 1 min. The relative expression of a specific gene was determined with the $2^{-\Delta\Delta CT}$ method. GAPDH was used as an internal control, and the primer sequences used are shown in Table 1.
Table 1
Primers used for qPCR

| Gene  | Primer sequence                   | Product size (bp) |
|-------|-----------------------------------|-------------------|
| Fas   |                                   |                   |
| Forward | 5'-ATGAGATCGAGCACAACAGC-3'    | 105               |
| Reverse| 5'-TTAAAGCTTGACACGCACCA-3'     |                   |
| FasL  |                                   |                   |
| Forward | 5'-TTCCGTGGGTTCTTC-3'     | 242               |
| Reverse| 5'-CCATGTCCTTTCTACCTGTCA-3'  |                   |
| Caspase3 |                                   |                   |
| Forward | 5'-GAAAGCCGAAACTCTTTCA-3'  | 155               |
| Reverse| 5'-ATAGTTACCAGGTGCAGTG-3'   |                   |
| Caspase8 |                                   |                   |
| Forward | 5'-TCCGTTTTATAGTTCCGCT-3'  | 186               |
| Reverse| 5'-GGTGGAGAGCGCTGTAACCTGT-3' |                   |
| GAPDH |                                   |                   |
| Forward | 5'-GGCTACACTGAGCTGTAACCTGT-3' | 142               |
| Reverse| 5'-TGCTGTAGCCATATTTTGCT-3'    |                   |

Western blotting

The spinal cord tissues were lysed with RIPA lysis buffer (Beyotime, China). Then the protein concentration was determined with the bicinchoninic acid (BCA) protein assay kit (Beyotime, China). 50 µg of protein was separated in each sample by 10% SDS polyacrylamide gel electrophoresis and then transferred onto a nitrocellulose (NC) membranes. After blocking in 5% milk in TBST for 1 h at room temperature, the membranes were incubated with primary antibodies against Fas (1:1000), caspase-3 (1:1000), and α-tubulin (1:1000) (Proteintech, China) or FasL (1:1000) (Servicebio, China) overnight at 4 °C. Then the membranes were incubated with horseradish-peroxidase-conjugated secondary antibodies (1:5000) (Cell Signaling, USA). Specific proteins were visualized using a chemiluminescence detection system, and the protein bands were quantified with the Image Lab software. The expression of Fas, FasL, and cleaved caspase-3 was normalized to that of α-tubulin as an internal reference.

Statistical analysis
All assays were performed at least in triplicate, and the data are presented as mean ± standard deviation (SD). When compared between groups the data were analysed with the *t* test, one-way ANOVA followed by post hoc Turkey test by SPSS software (version 25.0, IBM, USA). A value of *P* < 0.05 was considered statistically significant.

### 3 Results

The MWT of rats was increased by repeated intrathecal RH

The MWT at 3 days after intrathecal catheterization was similar to that before intrathecal catheterization (Fig. 2A, 2B; *P* > 0.05), but 1% and 2% RH groups had significantly higher MWT as compared to the saline group at 24 h after intrathecal administration (*P* < 0.05).

Repeated intrathecal RH affected the morphology of spinal cord

HE staining showed the spinal cord structure in each group was relatively complete. In the saline group, there were no morphological abnormalities. The mild edema of the posterior horn was observed in the spinal cord of 0.5% RH group, and significant edema was noted in the 1% and 2% RH groups. In addition, some vacuoles and nuclear membranes dissolution were observed in the spinal cord after repeated intrathecal use of RH (Fig. 3).

RH induced apoptosis in the spinal cord

The results showed a few apoptotic cells in the saline group. However, a lot of apoptotic cells were observed in the posterior horn of the spinal cord of RH groups (0.5%, 1% and 2%) (Fig. 4A). Compared with the saline group, the proportion of apoptotic cells in the posterior horn increased with the increase in the RH concentration (Fig. 4B, 4C; *P* < 0.05).

RH up-regulated mRNA expression of Fas, FasL, Caspase-8, and Caspase-3 in the spinal cord

As shown in Fig. 5A, 5B, 5C, the mRNA expression of Fas, FasL and caspase-8 increased significantly in RH groups (0.5%, 1%, 2%) compared with saline group (*P* < 0.05). There was no statistical difference between 0.5% RH group and saline group in the caspase-3 mRNA expression (*P* > 0.05), but caspase-3 mRNA expression in the 1% and 2% RH groups was significantly higher than in the saline group (Fig. 5D; *P* < 0.05).

RH increased protein expression of Fas, FasL, and cleaved caspase-3 in the spinal cord

Results showed intrathecal administration of RH at different concentrations (0.5%, 1% and 2%) for 12 h significantly increased the protein expression of Fas, FasL, and cleaved caspase-3 as compared to the saline group (Fig. 6; *P* < 0.05).

### 4 Discussion
Nerve injury is a complication of peripheral nerve blocking and spinal anesthesia. There are many factors related to the nerve injury, such as the high concentration LAs and inaccurate puncture for anesthesia. Increasing evidence shows that the neurotoxicity of LAs is an important risk factor to the nerve injury (17, 18). RH is frequently used in the epidural and spinal anesthesia. Compared with bupivacaine, RH can provide a good analgesic effect with less motor blockade. However, like other LAs, neurotoxicity of RH has been reported in some kinds of animal and cell experiments, and it is closely related to the nerve injury in some cases. However, the exact mechanism of RH neurotoxicity after intrathecal use is currently unclear, and no effective measures have been developed to prevent the nerve injury caused by RH.

In the present study, rats received repeated intrathecal administration of RH at different concentrations for 12 h, and the apoptosis in the spinal cord was assessed at 24 h after RH exposure. Our results showed rats treated with 1% or 2% RH developed symptoms of nerve injury, manifested by an increased MWT. Morphologically, edema and vacuolization increased in the posterior horn of the spinal cord after RH treatment, and the apoptosis rate of the spinal cord elevated with the increase in the RH concentration. This suggests that RH at a high concentration is more likely to induce apoptosis in the spinal cord and symptoms of nerve injury such as paresthesia, which is consistent with the relationship between LA concentration and incidence of nerve injury in the clinical practice (19). Moreover, the expression of Fas and FasL was up-regulated after RH administration, and the expression of caspase-3 and caspase-8 increased. It indicates that the Fas / FasL pathway is involved in RH induced neuronal apoptosis in the rat spinal cord, which is related to the neurotoxicity of RH.

Apoptosis has been proposed as an important mechanism of LA's neurotoxicity (20). Recent studies have shown that LAs can induce apoptosis through a variety of pathways. In addition to the Fas/FasL pathway, some investigators have reported that RH can reduce the mitochondrial membrane potential of human neuroblastoma SH-SY5Y cells, which decreases the cytochrome C activity and ATP production, thereby activating caspase-3 to induce apoptosis (21). Niu et al. revealed that RH reduced the expression of major mitochondrial regulator peroxisome proliferator-activated receptor gamma coactivator 1-alpha (PGC-1a) and its downstream transcription factors, then inducing the loss of mitochondrial function (22). Zheng et al. found RH induced poly-ADP ribose polymerases-1 (PARP-1) activation and nicotinamide adenine dinucleotide (NAD+) depletion in the SH-SY5Y cells, and induced PARP-1-dependent cell death via apoptosis (23). The study of Wang et al. showed that the miR-210 expression increased after bupivacaine treatment, and miR-210 could target the 3'UTR region of the neurotrophic factor brain-derived neurotrophic factor (BDNF), eventually inducing apoptosis (24). In addition to inducing apoptosis, LAs can also induce neurotoxicity by interfering with autophagy (25) and neuroinflammation (26).

Available studies have demonstrated the role of Fas/FasL in the apoptosis following spinal cord injury, and our study also showed Fas/FasL was involved in the neurotoxicity of RH. The expression of Fas/FasL was regulated via multiple signaling pathways (27, 28), and the specific mechanism by which LAs up-regulate Fas/FasL expression is still poorly understood. Sujan et al. revealed that the p38MAPK-p53-Fas-Caspases pathway played an important role in the regulation of anti-neoplastic activity of S-allyl cysteine (SAC) (29). Wang et al. found regulating p38 MAPK expression by siRNA technology
significantly reduced the Fas expression in the neurons such as rat pheochromocytoma PC12 cells and human glioma U87 cells (30). These results suggest that p38 MAPK/p53 may be an important molecular basis for the up-regulated Fas expression. Whether the p38MAPK-p53 signaling pathway is involved in the up-regulation of Fas/FasL expression in the rat spinal cord after RH is warranted to be further studied.

5 Conclusions

In summary, our study suggests that repeated intrathecal RH administration can induce symptoms of neurological damage, which may be related to the apoptosis in rat spinal cord via an Fas/FasL dependent manner. Our findings provide an experimental basis for the prevention and treatment of complications of LA neurotoxicity.
