Aims

Atrial fibrillation (AF) and heart failure (HF) are two growing epidemics that frequently co-exist. We aimed to gain insights into the underlying pathophysiological pathways in HF patients with AF by comparing circulating biomarkers using pathway overrepresentation analyses.

Methods and results

From a panel of 92 biomarkers from different pathophysiological domains available in 1620 patients with HF, we first tested which biomarkers were dysregulated in patients with HF and AF (n = 648) compared with patients in sinus rhythm (n = 972). Secondly, pathway overrepresentation analyses were performed to identify biological pathways linked to higher plasma concentrations of biomarkers in patients who had HF and AF. Findings were validated in an independent HF cohort (n = 1219, 38% with AF). Patient with AF and HF were older, less often women, and less often had a history of coronary artery disease compared with those in sinus rhythm. In the index cohort, 24 biomarkers were up-regulated in patients with AF and HF. In the validation cohort, eight biomarkers were up-regulated, which all overlapped with the 24 biomarkers found in the index cohort. The strongest up-regulated biomarkers in patients with AF were spondin-1 (fold change 1.18, P = 1.33 × 10−12), insulin-like growth factor-binding protein-1 (fold change 1.32, P = 1.08 × 10−9), and insulin-like growth factor-binding protein-7 (fold change 1.33, P = 1.35 × 10−18). Pathway overrepresentation analyses revealed that the presence of AF was associated with activation amyloid-beta metabolic processes, amyloid-beta formation, and amyloid precursor protein catabolic processes with a remarkable consistency observed in the validation cohort.

Conclusion

In two independent cohorts of patients with HF, the presence of AF was associated with activation of three pathways related to amyloid-beta. These hypothesis-generating results warrant confirmation in future studies.
In brief, BIOSTAT-CHF was a prospective, observational, multipool individual-patient data revealed Atrial fibrillation (AF). This study complies with the Declaration of Helsinki, and mediathrosis analysis, and can trigger each other. Distinct differences are observed when comparing patients with HF with and without AF. We recently showed that patients with AF and HF are older, less often have an ischaemic aetiology of HF, and have a distinct biomarker profile when compared with HF patients in sinus rhythm. Moreover, patients with AF and HF have a poorer quality of life and worse outcomes when compared with those without AF. Pooled individual-patient data revealed that in contrast to the beneficial effects observed in patients with HF with a reduced ejection fraction (HFrEF) in sinus rhythm, β-blockers did not improve clinical outcomes in patients with AF and HFrEF. The potential lack of β-blocker efficacy suggests differences in pathophysiology between HF patients with and without AF, but the exact mechanisms remain poorly understood and understudied.

Unravelling the underlying pathophysiology of AF in HF is important since this population might respond to different therapies than HF patients without AF. Underlying pathophysiological mechanisms can be studied by performing pathway overrepresentation analyses, a method that can identify associated pathways based on circulating biomarker profiles in specific subgroups. Therefore, we compared patients who had HF with and without AF, studied their biomarker profiles and associated pathophysiological pathways, which might help discover new treatment targets for patients with HF and AF.

### 1. Introduction

Atrial fibrillation (AF) is the most common arrhythmia in heart failure (HF) with a prevalence between 20% and 60% depending on the type and severity of HF. Both AF and HF are strongly associated with ageing, share many other clinical risk factors such as obesity and hypertension, and can trigger each other. Distinct differences are observed when comparing patients with HF with and without AF. We recently showed that patients with AF and HF are older, less often have an ischaemic aetiology of HF, and have a distinct biomarker profile when compared with HF patients in sinus rhythm. Moreover, patients with AF and HF have a poorer quality of life and worse outcomes when compared with those without AF. Pooled individual-patient data revealed that in contrast to the beneficial effects observed in patients with HF with a reduced ejection fraction (HFrEF) in sinus rhythm, β-blockers did not improve clinical outcomes in patients with AF and HFrEF. The potential lack of β-blocker efficacy suggests differences in pathophysiology between HF patients with and without AF, but the exact mechanisms remain poorly understood and understudied.

Unravelling the underlying pathophysiology of AF in HF is important since this population might respond to different therapies than HF patients without AF. Underlying pathophysiological mechanisms can be studied by performing pathway overrepresentation analyses, a method that can identify associated pathways based on circulating biomarker profiles in specific subgroups. Therefore, we compared patients who had HF with and without AF, studied their biomarker profiles and associated pathophysiological pathways, which might help discover new treatment targets for patients with HF and AF.

### 2. Methods

#### 2.1 Patient population

We performed a post hoc study of patients enrolled in A Systems Biology Study to Tailored Treatment in Chronic Heart Failure (BIOSTAT-CHF), of which the design and primary results have been published previously. In brief, BIOSTAT-CHF was a prospective, observational, multinational, European HF study, in which a total of 2516 patients were included. Patients were eligible with either a left ventricular ejection fraction (LVEF) <40% or plasma concentrations of N-terminal pro-B-type natriuretic peptide (NT-proBNP) >2000 ng/L. Another 1738 patients with HF were included in an independent cohort from six centres in Scotland, which we have used as our validation cohort. Patients were enrolled into the validation cohort when they were diagnosed with HF and had a previous documented admission with HF requiring diuretic treatment.

This study complies with the Declaration of Helsinki, and medical ethics committees of participating centres approved the study. All patients provided written informed consent.

#### 2.2 Definitions

Patients were classified as AF when they met the following criteria: (i) a documented history of AF and (ii) AF registered on the standard 12-lead electrocardiogram (ECG) at baseline of the study. Patients were classified as having sinus rhythm when they met the following criteria: (i) no documented history of AF and (ii) sinus rhythm on the baseline ECG. Patients with a pacemaker rhythm (n = 320) or unknown rhythm (n = 58) were excluded from our analyses. Patients with prior episodes of AF but who were in sinus rhythm at baseline (n = 197) and those without a history of AF but with AF on the baseline ECG (n = 82) were...
excluded from our analyses, since these patients could interfere with the contrast in underlying pathophysiological pathways between the AF and sinus rhythm groups under study. We did include these patients in a previous biomarker study on AF in BIOSSTAT-CHF, but since subsequent analyses revealed that many biomarkers tend to fluctuate with paroxysmal episodes of AF, we chose to include HF patients with ‘permanent’ AF when compared with those who never had any previously documented episode of AF in the current analyses. A flow chart of the selected patients is displayed in Supplementary material online, Figure S1.

2.3 Biomarkers
The Olink Cardiovascular III panel includes 92 biomarkers from different pathophysiological domains. The Proseek Multiplex 96 × 96 kit of Olink Bioscience (Uppsala, Sweden) analysis service was used, which measured the 92 biomarkers in 1 μl plasma samples. The reagents are based on the Proximity Extension Assay technology, which binds 92 oligonucleotide-labeled antibody probe pairs to the target biomarker.”

For further quantification, real-time PCR was performed. Olink wizard and GenEx software were used for further data analysis. Proseek data are presented as arbitrary units on a log2 scale (Supplementary material online, Tables S1 and S2). Complete biomarker data were available in 87% of the patients under study.

2.4 Statistical analyses
Normally distributed continuous variables were displayed as mean ± standard deviation, non-normally distributed variables as median with the first and third quartile (Q1–3). Categorical variables were presented as numbers with percentages. Group comparisons were tested using Student’s t-tests, Mann–Whitney U tests, or χ² tests where appropriate. Differences in expression of the 92 biomarkers between patients with AF vs. sinus rhythm were tested using Linear Models for Microarray data analysis (Limma) software (version 3.34.9), using a log2 fold change cutoff of 0.2, and a false discovery rate <0.05 according to the Benjamini–Hochberg method. The biomarkers that were up-regulated in patients with AF compared to those in sinus rhythm was further studied using pathway overrepresentation analysis. Pathway overrepresentation analysis was performed with knowledge from established pathways in publicly available databases: Gene Ontology, Reactome, and the Kyoto Encyclopedia of Genes and Genomes (KEGG) using Cytoscape (version 3.7.1) and plugin ClueGO (version 2.5.4). Multivariable logistic regression was performed to study the association between the biomarkers within pathways and AF status, adjusting for age, sex, body mass index (BMI), heart rate, a history of coronary artery disease, and renal disease. Since we were interested in underlying pathophysiological differences between patients with HF with a reduced/mid-range/preserved ejection fraction HFrEF/HFmrEF/HFpEF, we performed the same analyses in these subgroups. Unfortunately, these subgroups were too small to gain results with pathway overrepresentation analyses. This was still the case when we analysed only two groups: LVEF <45% vs. LVEF ≥45%. We therefore tested for interactions to determine whether the association of biomarkers and AF status was present in patients with HFrEF/HFmrEF/HFpEF by adding the interaction term to the logistic regression model and also tested for an interaction with LVEF on a continuous scale. A separate network analysis focusing on pathophysiological differences between patients with HFpEF and HFrEF has been published previously. A P-value smaller than 0.1 was considered statistically significant for testing interactions. All other tests were performed two-sided, and a P-value of <0.05 was considered statistically significant. Statistical analyses were conducted using R, A Language and Environment for Statistical Computing, version 3.5.3 (R Foundation for Statistical Computing, Vienna, Austria).

3. Results
3.1 Index cohort
3.1.1 Clinical characteristics
Of 1620 patients with HF enrolled, 648 (40%) had AF and 972 (60%) were in sinus rhythm. Patients with AF were older, less often women, had a higher BMI and a higher heart rate (Table 1). Fewer patients with AF had a history of coronary artery disease, but more often a history of renal disease when compared with those in sinus rhythm. Patients with AF had larger left atrial diameters, and greater interventricular and posterior wall thickness on echocardiography.

3.1.2 Biomarker concentrations
In the index cohort, 24 biomarkers were up-regulated and three biomarkers were down-regulated in patients with AF as compared to those in sinus rhythm (Figure 1). A volcano plot with the up- and down-regulated biomarkers is presented in Figure 2A. The three biomarkers that were most significantly differentially expressed in patients with AF when compared with those in sinus rhythm were neurogenic locus notch homolog protein 3 (NOTCH3, fold change 1.30, P = 6.40 × 10⁻¹³), insulin-like growth factor binding protein-7 (IGFBP-7, fold change 1.33, P = 1.35 × 10⁻¹⁸), and interleukin-1 receptor-like 1 (IL1RL1, fold change 1.35, P = 1.75 × 10⁻¹⁶) (Supplementary material online, Table S1).

3.1.3 Pathway overrepresentation analyses of up-regulated biomarkers
Pathway overrepresentation analyses of the 24 up-regulated biomarkers in the index cohort revealed seven pathways that were dysregulated specifically in patients with AF: (i) amyloid-beta metabolic process, (ii) amyloid-beta formation, (iii) amyloid precursor protein catabolic process, (iv) regulation of insulin-like growth factor (IGF) transport and uptake, (v) membrane protein ectodomain proteolysis, and (vii) regulation of neuroinflammatory response (Figure 3).

3.2 Validation cohort
3.2.1 Clinical characteristics
The baseline characteristics of patients included in the smaller validation cohort are presented in Table 2. In general, patients enrolled in the validation cohort were older, had a higher LVEF, and lower plasma concentrations of NT-proBNP when compared with patients included in the index cohort. However, similar trends were observed in patients with AF compared to those in sinus rhythm, in which patients with AF were older, less often women, had higher heart rates, and less often a history of coronary artery disease.

3.2.2 Biomarker concentrations
In the validation cohort, eight biomarkers were significantly up-regulated in patients with AF, all of which overlapped with the 24 biomarkers that were found to be significantly up-regulated in the index cohort (Figure 1). The eight biomarkers that were up-regulated in AF patients in both HF cohorts included IGFBP-7 (fold change 1.30, P = 5.13 × 10⁻¹⁸), NOTCH3 (fold change 1.25, P = 1.44 × 10⁻¹⁴), spondin-1 (SPON1, fold change 1.18, P = 1.29 × 10⁻¹²), IL1RL1 (fold change 1.31, P = 1.75 × 10⁻¹⁶).
Table 1  Baseline characteristics of patients included in the index cohort

| Clinical | Atrial fibrillation, n = 648 (40%) | Sinus rhythm, n = 972 (60%) | P-values |

Coronary artery disease: previous myocardial infarction, percutaneous coronary intervention (PCI), and/or coronary artery bypass graft (CABG).
3.2.3 Pathway overrepresentation analyses of up-regulated biomarkers

Pathway overrepresentation analysis of the eight up-regulated biomarkers in patients with AF in the validation cohort revealed three activated pathways: (i) amyloid-beta metabolic process, (ii) amyloid-beta formation, and (iii) amyloid precursor protein catabolic process (Figure 3).

3.2.4 Overlap index and validation cohort

The three amyloid-beta-related pathways were found in both the index and validation cohort, and were related to three up-regulated biomarkers in patients with AF: SPON1 (fold change 1.18, \( P = 1.33 \times 10^{-13} \)), IGFBP-1 (fold change 1.32, \( P = 1.08 \times 10^{-4} \)), and IGFBP-7 (fold change 1.33, \( P = 1.35 \times 10^{-18} \)). After adjusting for the clinical covariates: age, sex, BMI, heart rate, a history of coronary artery disease, and renal disease, the concentrations of SPON-1, IGFBP-1, and IGFBP-7 remained
associated with the presence of AF (all \( P < 0.001 \)), in both the index and the validation cohort. These associations were similar among HF phenotypes (HFrEF/HFmrEF/HFpEF; \( P \) for interaction = 0.42) and across LVEF as a continuous variable (\( P \) for interaction = 0.96).

4. Discussion

We sought to identify pathophysiological pathways in HF patients with AF using pathway overrepresentation analyses. In two independent HF cohorts, we found that the presence of AF was associated with amyloid-beta metabolic processes, amyloid-beta formation, and amyloid precursor protein catabolic processes. These three pathophysiological pathways were found based on higher levels of SPON1, IGFBP-1, and IGFBP-7 in those with AF. In the larger index cohort, four more pathophysiological pathways were found, which were not observed in the independent validation cohort. Previous studies investigating specific phenotypes or subgroups in HF (e.g. diabetes, ischaemic HF, old vs. young, and HFpEF vs. HFrEF) have not revealed any amyloid-beta-related pathways despite using the same methodology, which supports that the current findings might be specific to the presence of AF in patients with HF.\(^{10,11,17}\)

4.1 Individual biomarkers

In the present study, the concentrations of SPON-1, IGFBP-1, and IGFBP-7 were closely linked to the three amyloid-beta-related pathways. Although IGFBP-1 and IGFBP-7 are linked to a wide range of biological processes associated with inhibition and stimulation of cell growth, the current knowledge indicates a more specific role for SPON-1.\(^{18}\) SPON-1 is an extracellular matrix cell adhesion glycoprotein that is expressed in multiple organs including the heart and brain.\(^{18}\) The SPON-1 protein binds to the extracellular domain of amyloid precursor protein and inhibits beta-secretase cleavage of this amyloid precursor protein, a process that is strongly related to the formation of amyloid-beta deposits.\(^{19}\) In a large genome-wide association study investigating the rate of cognitive decline in patients with Alzheimer’s disease, the most interesting candidate gene identified was SPON-1, since it was strongly associated with the rate of cognitive decline in two independent cohorts.\(^{20}\) Recent studies showed that increased levels of IGFBP-7, a marker of ageing and cellular senescence, were strongly associated with increased left atrial size, and the presence of AF in patients with HF.\(^{21,22}\) In Framingham Heart Study participants without HF, increased levels of IGFBP-1 were strongly associated with incident AF.\(^{23}\) In the present study, NOTCH3 was strongly up-regulated in patients with AF in both cohorts. The

⁴Coronary artery disease: previous myocardial infarction, percutaneous coronary intervention (PCI), and/or coronary artery bypass graft (CABG).
In the heart specifically, NOTCH signalling has been suggested to be associated with repair of infarcted and overloaded myocardium, but this has only been investigated in a pre-clinical setting. The role of the NOTCH system in patients with AF and HF is yet to be elucidated.

### 4.2 Amyloid-beta in HF and AF
Cardiac amyloidosis has been reported to be associated with a high prevalence of AF in several previous studies, however, prior work focused on isolated atrial amyloidosis (IAA) and transthyretin-derived amyloidosis (ATTR)—the most commonly described forms of cardiac amyloidosis in elderly patients. Our results concerned amyloid-beta depositions, which are generally acknowledged as a hallmark of Alzheimer’s disease, in which abnormal cleavage of the amyloid precursor protein leads to pathological amyloid-beta fragments, protein aggregation, and formation of extracellular plaques that can lead to degradation of neurons. Even though Alzheimer’s disease has been traditionally considered as a brain-specific disease, recent discoveries suggest that other organs might also be involved in the pathophysiology, suggesting that Alzheimer’s disease might be a focal manifestation of a systemic disorder. The epidemiological link between AF and Alzheimer’s disease was first described in 1977, followed by studies showing that younger patients with AF had an increased risk of developing all-cause dementia, which could not be explained by the increased incidence of stroke alone. Since then, contradictory results have been reported, but neuropathological analyses of autopsies did reveal a higher incidence of amyloid-beta plaques and amyloid angiopathy in the brains of patients with permanent AF. Suggesting a unifying pathogenesis, Troncone et al. performed a cross-sectional study investigating cardiac involvement of patients with a primary diagnosis of Alzheimer’s disease as compared to age-matched controls. Indeed, those with Alzheimer’s disease had increased left ventricular septal and inferolateral wall thickness on echocardiography, and expression of amyloid-beta plaques in both the heart and the brain.

### 5. Conclusion
In two independent cohorts of patients with HF, the presence of AF was associated with amyloid-beta metabolic processes, amyloid-beta formation, and amyloid precursor protein catabolic processes, based on higher amyloid-beta hypothesis. Future research in cases (patients with AF + HF) and controls (patients in sinus rhythm with and without HF) with markers derived from atrial tissue will provide more direct insights into our hypothesis. Another limitation concerns the selected biomarker panel, which did cover many pathophysiological domains but was primarily a cardiovascular disease-related biomarker panel. The number of significantly up-regulated biomarkers was higher in the index cohort than in the validation cohort, which resulted in more associated pathophysiological processes in the index cohort than in the validation cohort. This could be the consequence of the larger number of patients included in the index cohort, the different inclusion criteria of patients that were used for the two independent cohorts, or the different regions of inclusion of the study participants (11 European counties vs. six centres in Scotland). The use of amiodarone was higher in the index cohort compared with the validation cohort. However, despite these differences between the two cohorts, all up-regulated biomarkers and pathways found in the validation cohort overlapped with those found in the index cohort. The HF/EF, HFmrEF, and HFpEF subgroups were unfortunately too small to yield results with pathway overrepresentation analyses. There was, however, no interaction between the amyloid-beta-related biomarkers and the HF subgroups, suggesting a pathophysiological role of amyloid-beta in HF patients across the full LVEF spectrum. Not all (combinations of) biomarkers were annotated by the publicly available databases even though these biomarkers were deemed to be significantly up- or down-regulated in our analyses (e.g. NOTCH3 and IL1RL1), since the content of these databases is based on what is currently known about these biomarkers. Therefore, the results of the current pathway overrepresentation analyses might change over time, when the knowledge on the (combination of) biomarkers has increased. The current findings might reflect underlying pathophysiological processes specific to elderly patients with AF and HF, since the mean age of these patients was 72 and 75 years in the two cohorts, respectively. The number of women included in the cohorts was limited (n = 462 (index) and n = 439 (validation), 32%) and mainly comprised postmenopausal women. Even though we have attempted to define the AF and sinus rhythm group mutually exclusive, it is possible that patients with asymptomatic paroxysmal AF were misclassified. Based on the current definition, we may have predominantly included patients with persistent/permanent AF and less patients with paroxysmal AF. Moreover, we do not have data on the duration of AF since no continues rhythm monitoring was incorporated in the study protocol, which might have influenced the biomarker concentrations. Unfortunately, we also do not have information on cognitive function, other neurologic diseases, nor information on systemic or cardiac amyloidosis of patients enrolled in BIOSTAT-CHF, which could have strengthened our hypothesis linking AF–HF to Alzheimer’s disease and/or amyloidosis. As with all cross-sectional studies, we cannot prove causality.
level of SPON1, IGFBP-1, and IGBPBP-7 in those with AF. These hypothesis-generating results warrant confirmation in future studies.

Translational perspective

Using an unbiased approach, we identified and validated dysregulation of three amyloid-beta-related pathways in patients who had heart failure (HF) with concomitant atrial fibrillation (AF). Amyloid-beta depositions are a hallmark of Alzheimer’s disease, but might also play a role in pathophysiological processes outside the central nervous system. Biochemical studies are needed to confirm the pathophysiological role of amyloid-beta in patients with AF and HF. Diagnostic and therapeutic implications should be investigated in the light of potential pathophysiological overlap between the three ageing-related epidemics: Alzheimer’s disease, AF, and HF.
