6 February 2019

ABSTRACT

One of the most important parameters in characterising the Epoch of Reionization, the escape fraction of ionizing photons, \(f_{\text{esc}}\), remains unconstrained both observationally and theoretically. With recent work highlighting the impact of galaxy-scale feedback on the instantaneous value of \(f_{\text{esc}}\), it is important to develop a model reionization is self-consistently coupled to galaxy evolution. In this work, we present such a model and explore how physically motivated functional forms of \(f_{\text{esc}}\) affect the evolution of ionized hydrogen within the intergalactic medium. Using the 21cm power spectrum evolution, we investigate the likelihood of observationally distinguishing between a constant \(f_{\text{esc}}\) and other models that depend upon different forms of galaxy feedback. We find that changing the underlying connection between \(f_{\text{esc}}\) and galaxy feedback drastically alters the large-scale 21cm power. The upcoming Square Kilometre Array Low Frequency instrument possesses the sensitivity to differentiate between our models at a fixed optical depth, requiring only 200 hours of integration time focused on redshift \(z = 7.5 - 8.5\). Generalizing these results to account for a varying optical depth will require multiple 800 hour observations spanning redshift \(z = 7 - 10\). This presents an exciting opportunity to observationally constrain one of the most elusive parameters during the Epoch of Reionization.

Key words: dark ages, reionization, first stars - galaxies: high redshift - intergalactic medium

1 INTRODUCTION

The Epoch of Reionization, which is completed by redshift \(z \sim 6\) (Fan et al. 2006; Becker et al. 2015), represents the final phase transition of the Universe from a neutral, post-recombination state to the highly ionized one that we observe today. As the first stars form they radiate photons which gradually ionize the neutral hydrogen within the intergalactic medium (IGM). During reionization an intense ultraviolet background (UVB) builds up, photo-heating the IGM and evaporating baryons within low mass dark matter halos (Shapiro et al. 2004). For the galaxies residing in these halos, star formation is severely suppressed and often halted. As these galaxies provide the starting conditions for the Universe we see today, it is paramount to understand the interplay between the Epoch of Reionization and galaxy evolution.

An important parameter for understanding the Epoch of Reionization is the fraction of hydrogen ionizing photons that escape from galaxies into the IGM, \(f_{\text{esc}}\). This parameter strongly dictates the speed and duration of reionization, in addition to affecting the size and topology of the ionized regions. Since the ionizing flux is absorbed by the intervening neutral IGM, observationally measuring \(f_{\text{esc}}\) during the Epoch of Reionization is not possible. At lower redshifts where direct measurement is not precluded, there is some consensus on the value of \(f_{\text{esc}}\). Within this regime (redshift \(0 < z < 1.5\)), escape fractions on the order of \(\sim 0.01\) have been predominantly observed (e.g., Grimes et al. 2009; Cowie et al. 2009; Siana et al. 2010). As redshift increases to \(z \sim 4\), \(f_{\text{esc}}\) has been observed to range from 0.01-0.05 (e.g., Vanzella et al. 2010; Guaita et al. 2016; Grazian et al. 2016)\footnote{However, also note outlying measurements of (e.g.,) \(f_{\text{esc}} > 0.28\) at redshift \(z = 2.5\) (Bian et al. 2017)}. Even with a number of observational measurements, it is still uncertain exactly how \(f_{\text{esc}}\) varies with galaxy properties.

Based mostly on radiation-hydrodynamical simula-

tions, there exists a growing body of work that highlights the importance of galaxy-scale processes in regulating the instantaneous value of $f_{esc}$. Paardekooper et al. (2015) finds that the spatial distribution of gas inside a halo can dictate the values of $f_{esc}$. Importantly, they find that processes such as supernovae feedback are able to disperse dense gas clouds and permit the easy escape of ionizing photons. This was confirmed by Kimm et al. (2017) and Trebitsch et al. (2017) where the simulations show that this process is most efficient in low mass galaxies and Trebitsch et al. (2017) where the simulations show that this process is most efficient in low mass galaxies. This picture, that gas is easily expelled due to the low gravitational potential. This picture, that gas is easily expelled due to the low gravitational potential.

Importantly, they find that processes such as supernovae feedback are able to disperse dense gas clouds and permit the easy escape of ionizing photons. In an effort to quantify the impact of $f_{esc}$ on parameters such as the duration of reionization and topology of ionized regions, a number of works have analysed reionization models under different values and functional forms of $f_{esc}$. Bauer et al. (2015) post-process a radiative transfer scheme with the hydrodynamic Illustris simulation and show that the duration of reionization varies between 190 to 340Myr if $f_{esc}$ scales with redshift. Similar results are echoed by Doussot et al. (2017) who use a self-consistent radiative-hydrodynamic simulation to follow the evolution of ionized hydrogen for an $f_{esc}$ value that scales linearly or quadratically with redshift. There have been few works investigating the impact of $f_{esc}$ on the topology of ionized regions. The most relevant is Kim et al. (2013) who show that by employing $f_{esc}$ values that vary with halo mass or redshift, the resulting size and distribution of ionized regions differ noticeably. Such a result highlights that the functional form of $f_{esc}$ plays a key role in setting the topology of ionized hydrogen during reionization.

One of the most promising avenues in detecting the Epoch of Reionization and its topology is through measurement of the low frequency 21cm hydrogen line with radio telescopes such as the Murchison Widefield Array (MWA, Tingay et al. 2013), Square Kilometre Array (SKA, Carilli & Rawlings 2004), Low Frequency Array (LOFAR, van Haarlem et al. 2013) and Hydrogen Epoch of Reionization Array (HERA, DeBoer et al. 2017). Importantly, these instruments will measure the 21cm transition on a range of scales with the signal intensity depending upon the presence of neutral hydrogen. Hence to fully exploit the scientific power of these next generation telescopes, we require accurate models detailing the evolution of ionized hydrogen during the Epoch of Reionization.

The coupling between $f_{esc}$ and galaxy feedback should significantly impact both the duration of reionization and topology of ionized regions. Furthermore, this coupling could have important consequences for the 21cm power spectrum which could affect the detectability of the Epoch of Reionization. In this paper we attempt to self-consistently model such coupling with the Reionization using Semi-Analytic Galaxy Evolution (RSAGE) model. Using galaxies as the source of ionizing photons and following the evolution of ionized hydrogen, the RSAGE framework self-consistently accounts for reionization feedback by suppressing the infall of baryons onto low mass galaxies. We are able to calculate $f_{esc}$ values that depend uniquely upon galaxy properties, quantifying the impact the functional form of $f_{esc}$ has on the optical depth, duration of reionization and the 21cm power spectrum. We propose a new diagnostic plot that tracks the large and small scale 21cm power throughout reionization. This plot has the potential to distinguish between different functional forms of $f_{esc}$ and identifies the SKA observational sweet spot where such differences are maximal.

The paper is organised as follows: In Section 2 we outline the RSAGE model, highlighting the semi-numerical scheme we use to follow the evolution of ionized hydrogen within the IGM. Section 3 provides an overview of the $f_{esc}$ models we analyse in this work. In Section 4 we compare the history and duration of reionization for each $f_{esc}$ model. We then explore avenues to distinguish between $f_{esc}$ models in Section 5, where we show the differences in ionized region topology and evolution of the 21cm power spectra. We provide an overview of the model caveats in Section 6 and conclude in Section 7.

Throughout this paper we adopt the cosmological values $(h, \Omega_m, \Omega_{\Lambda}, \sigma_8, n_s) = (0.681, 0.302, 0.698, 0.828, 0.96)$ consistent with Planck Collaboration et al. (2016), and use a Chabrier (2003) initial mass function (IMF) where required.

## 2 SIMULATING REIONIZATION

In this Section, we summarize our simulation and the modelling procedures. We begin with a description of the collisionless N-body simulation used as an input, then provide an overview of our semi-analytic galaxy formation model adapted to high redshift. In particular, we elaborate on the self-consistent coupling between galaxy evolution and ionized hydrogen during the Epoch of Reionization.

### 2.1 N-Body Simulation

In order to capture the evolution of galaxies over cosmic time, we derive the growth and merger histories of their host dark matter halos from the N-Body simulation Kali (Seiler et al. 2018). Kali contains 2400 dark matter particles within a 160Mpc side box, resolving halos of mass $\sim 4 \times 10^{10} M_\odot$ with 32 particles. The particles were evolved using GADGET-3 (Springel et al. 2005) with 98 snapshots of data stored between redshifts $z = 30-5.5$ in 10Myr spaced intervals. We refer the interested reader to Seiler et al. (2018) for more information regarding the Kali initial conditions and merger tree construction.

### 2.2 Semi-Analytic Galaxy Modeling

Within RSAGE, the evolution of galaxies over cosmic time uses the Semi-Analytic Galaxy Evolution (SAGE) model of Croton et al. (2016, hereafter C16) as a base. The SAGE model includes baryonic accretion, cooling, star

---

formation, gas ejection due to supernova feedback, active galactic nuclei feedback through ‘radio mode’ heating and ‘quasar mode’ gas ejection, and galaxy mergers. In this work, the only galaxy model prescriptions we have changed with respect to C16 are the supernova and reionization feedback schemes, explained below.

In the C16 model, supernova feedback is applied instantaneously. That is, following a star formation episode, a fraction of stars immediately explode, reheating cold gas and ejecting hot gas. Whilst such an approximation is valid at low redshift where the time between snapshots is larger than the lifetime of a supernova candidate star, the same is not true during the Epoch of Reionization. Instead, we closely follow Mutch et al. (2016) and release energy from supernova activity gradually over a number of subsequent snapshots. This results in a much smoother and physically motivated ejection history for each galaxy.

To model the effect of reionization on the evolution of galaxies, C16 implements an analytic prescription using fits to the hydrodynamic simulations of Gnedin (2000). Importantly, this prescription adopts the parametrization of Kravtsov et al. (2004) which uses the redshift at which the first HII regions overlap and the redshift when reionization is completed. As this parameterization is universal, it ignores the effect of inhomogenous reionization and switches reionization ‘on’ for all galaxies regardless of mass or environment. We describe our new reionization feedback scheme in Section 2.3.

Whilst C16 utilized a primary and secondary set of constraints to choose their fiducial set of parameters, here we adjust the galaxy evolution parameters manually to match the high redshift stellar mass function using González et al. (2011), Duncan et al. (2014) and Song et al. (2016) between $z = 6 - 8$ (Figure 1). This involved altering the following C16 parameters: the star formation rate efficiency $\alpha_{\text{SF}}$ from 0.05 to 0.03 and the quasar mode ejection efficiency $\kappa_{\text{Q}}$ from 0.005 to 0.02. We use the Mutch et al. (2016) mass loading and energy coupling constants for supernova feedback and note that these values are scaled depending upon the host halo properties. Even with such minimal changes to the parameter values, Figure 1 shows that the stellar mass function matches the observations well over all redshifts, highlighting RSAGE’s robustness in modelling galaxy evolution during the Epoch of Reionization.

![Figure 1](image_url). Stellar mass function at redshift $z = 6, 7, 8$ using the RSAGE model. This model differs from C16 by using delayed supernova feedback and includes self-consistent reionization feedback. For clarity, we show here only the Constant model as all other models (Section 3) have very similar values by choice. Parameters were chosen to match observations from González et al. (2011), Duncan et al. (2014) and Song et al. (2016). All observations have been corrected to a Chabrier IMF and a Hubble parameter $h = 0.698$.

2.3 Self-Consistent Reionization

The initial works of Couchman & Rees (1986) and Efstathiou (1992) highlighted that the presence of an ultraviolet background (UVB) has significant consequences for galaxy evolution. By photo-heating gas within the IGM to temperatures above $10^{6}\text{K}$, the UVB acts to increase the Jeans mass for galaxies located within ionized regions causing a severe decrease in star formation. Furthermore, as ionization fronts sweep across the IGM, gas within low mass ($\sim 10^{7} - 10^{8}\text{M}_{\odot}$) halos is photo-heated and subsequently evaporated (Shapiro et al. 2004). Through these two mechanisms, galaxies embedded within the ionized IGM can have their evolution severely stunted. As the galaxies formed during this early epoch provide the initial conditions for subsequent galaxy assembly, understanding the evolution of ionized gas during the Epoch of Reionization and its impact on galaxy evolution is critical.

To address this, RSAGE includes a coupled treatment of reionization and its associated feedback on galaxy evolution. In our model, we use the semi-numerical code cifog (Hutter 2018) to generate an inhomogeneous UVB and follow the evolution of ionized hydrogen during the Epoch of Reionization. By using the galaxies simulated from RSAGE as ionizing sources, we are able to follow both galaxy formation and the progression of reionization in a self-consistent manner. To achieve this, we iterate through the Kali simulation snapshots and implement the following algorithm:

(i) Galaxies are evolved to the end of the current snapshot using the RSAGE galaxy evolution model as described in Section 2.2. Using each star formation history, the number of ionizing photons produced by each galaxy is calculated. Combined with the escape fraction of ionizing photons (Section 3), RSAGE then generates a grid of ionizing sources.

(ii) By comparing the number of HI ionizing photons with the number of neutral hydrogen atoms and adjusting for recombinations and self-shielding, cifog determines
the ionization state and local UVB strength within each grid cell.

(iii) RSAGE tracks the redshift at which each grid cell is ionized and generates a suppression modifier for dark matter halos within these cells. The baryonic content of halos within ionized regions is suppressed using this modifier and RSAGE proceeds to the next snapshot by cycling back to step (i).

In the following sub-sections we elaborate on each of these three steps.

### 2.3.1 Ionizing Photons

The number of ionizing photons that escape from each galaxy in the simulation is determined by the number of ionizing photons intrinsically produced \( N_{\gamma,i} \) and the escape fraction \( f_{esc,i} \) (see Section 3 for our models of \( f_{esc} \)),

\[
N_{\text{ion}} = \sum_i N_{\gamma,i} f_{esc,i},
\]

(1)

where \( N_{\gamma} \) is the number of ionizing sources (i.e., the number of galaxies).

Previously, we linked the value of \( N_{\gamma} \) to a galaxy’s star formation rate across each snapshot (Seiler et al. 2018). However, as star formation can be completely shut down as producing no ionizing photons. In our updated version of RSAGE, we instead link the number of ionizing photons produced by each galaxy to its star formation history. In a similar manner to the delayed supernova scheme, we store the past 100\,Myr of star formation in step sizes of 1\,Myr\(^3\). By using spectra generated from STARBURST99 (Leitherer et al. 1999) with a Chabrier (2003) initial mass function, we determine the number of ionizing photons, \( N_{\gamma,i} (M_{\text{burst}}) \), emitted from an instantaneous starburst that formed mass \( M_{\text{burst}} \) of stars. In practice, as \( M_{\text{burst}} \) and scale our results for any arbitrary star formation episode. The number of ionizing photons emitted from a galaxy at any given time \( t \) is then given by

\[
N_{\gamma} (t) = \sum_{t_i=1,2,3,...}^{100} \frac{N_{\gamma} (M_{\text{burst}} (t_i))}{10^6 M_\odot} \times \frac{M_{\text{burst}} (t_i)}{10^6 M_\odot},
\]

(2)

where \( M_{\text{burst}} (t_i) \) is the mass of stars formed \( t_i \)\,Myr ago.

### 2.3.2 The Reionization of Neutral Hydrogen

Once the number of ionizing photons for each galaxy has been determined, we follow the evolution of ionized gas using the grid-based code cifog; a newly developed, publicly available MPI-parallelised semi-numerical code which models the ionization of both hydrogen and helium. We summarize here the main features of cifog and refer the interested reader to Hutter (2018) for a detailed description of the code.

In order to flag ionized regions within the IGM, cifog uses the excursion set formalism approach of Furlanetto et al. (2004) in which a region is flagged as ionized (\( \chi_{HI} = 0 \)) if the number of ionizing photons exceeds the number of absorptions, otherwise it is marked as neutral (\( \chi_{HI} = 1 \)). Beginning at large radii and progressing towards small scales, the criterion on whether the central cell is flagged as ionized at redshift \( z \) is,

\[
\int_z^\infty N_{\text{ion}} (z) \, dz \geq \int_z^\infty N_{\text{abs}} (z) \, dz, \]

\[
\geq \langle \rho_{\text{H},0} \rangle_{R_{\text{cell}}} V_{\text{cell}} \left[ 1 + \int_z^\infty \left\langle N_{\text{rec}} \right\rangle_{R} (z) \, dz \right] , \quad (3)
\]

where \( n_{\text{H},0} \) is the hydrogen number density today, \( V_{\text{cell}} \) is the comoving volume of a grid cell, \( N_{\text{rec}} \) is the number of recombinations and \( \left\langle N \right\rangle_{R} \) denotes the average over the spherical region with radius \( R \). Provided the radius over which the ionizing photons and recombinations are counted is large enough, this method automatically accounts for ionization from neighbouring or distant bright sources.

To calculate the suppression of baryonic gas infall (Section 2.3.3), cifog must calculate the spatially dependent photoionization rate, \( \Gamma_{\text{HI}} (x, z) \). The photoionization rate represents the number of ionization events per unit time and is a function of the ionizing flux incident upon each grid cell,

\[
\Gamma_{\text{HI}} (x, z) \propto \sum_{t_i=0}^{100} \frac{N_{\gamma,i} (M_{\text{burst}} = 10^6 M_\odot)}{4\pi |x - x_i|^2 e^{-|x - x_i|/\lambda_{mfp}}} , \quad (4)
\]

where \( x = (x, y, z) \) is the position of the ionizing source and we perform the sum over all \( N_{\gamma} \) sources. \( \lambda_{mfp} \) is the median value of the mean free path of ionizing photons which, during reionization, is given by the size of ionized regions (i.e., the largest scale, \( R \), at which the excursion set formalism marks a region as being ionized). Towards the final stages of reionization, when ionized regions begin to merge, \( \lambda_{mfp} \) is instead given by the distance between self-shielded regions.

\(^3\) The SAGE model supports the use of sub-steps. Hence, whilst the time between \( K:\)h\ snapshots is 10\,Myr, galaxies are evolved in 1\,Myr time steps.

\(^4\) Available at https://github.com/annehutter/grid-model
2.3.3 Suppression of Baryonic Infall

As mentioned previously, the presence of an UVB can suppress star-formation by increasing the Jeans mass and photo-evaporating gas within low mass halos. By running a suite of 1D cosmological collapse simulations, Sobacchi & Mesinger (2013) capture these effects through their impact on the universal halo baryon fraction, $f_b$. They provide a parameterization whereby halos within ionized regions have their baryon fraction suppressed by a factor of $f_{mod}$,

\[ f_{mod}(M_H) = 2^{-2M_{crit}/M_H}, \]

where $M_H$ is the halo mass and $0 \leq f_{mod} \leq 1$. Here $M_{crit}$ is defined as the halo mass that is able to retain half of its baryons in the presence of an UVB (i.e., $f_{mod} = 0.5$). This value depends on the halo mass, UVB intensity ($\Gamma_H$), current redshift ($z$) and the redshift at which the surrounding IGM was ionized ($z_{reion}$),

\[ M_{crit} = M_0 \Gamma_H \left( \frac{1+z}{10} \right)^b \left[ 1 - \left( \frac{1+z}{1+z_{reion}} \right)^c \right]^d, \]

where $(M_0, a, b, c, d)$ are fitting parameters of the Sobacchi & Mesinger (2013) model and found to be $(2.8 \times 10^9 M_0, 0.17, -2.1, 2.0, 2.5)$.

Within RSAGE, we track the redshift at which each cell in the simulation box becomes ionized. From Equations 4 and 6, we generate a list of baryon modifiers (Equation 5) for all halos within ionized regions and suppress the baryonic content for the hosted galaxies according to the photoionization rate in each cell (Equation 4).

3 THE IONIZING ESCAPE FRACTION

In this Section, we describe our different models of the ionizing escape fraction, each depending on a different galaxy property or process. We provide a summary in Table 1. Whilst our coupled model offers the ability to investigate the effect of galaxy formation physics on reionization, here we focus explicitly on how the functional form of $f_{esc}$ impacts the timing and topology of reionization. Hence, we use identical parameters for the galaxy evolution aspect of RSAGE (Section 2.2) for each model. The free parameters for each model (shown in the ‘Calibration Values’ column of Table 1) are adjusted to ensure that the galaxy stellar mass function from redshift $z = 6-8$ matches the observations of González et al. (2011), Duncan et al. (2014) and Song et al. (2016). We also ensure the ionizing emissivity from redshift $z = 6-15$ matches the inferences of Bouwens et al. (2015) and the Thomson optical depth matches the measurements of Planck Collaboration et al. (2018).

**Constant:** This fiducial model uses a constant value of $f_{esc}$ for all galaxies over cosmic time,

\[ f_{esc} = \text{Constant}. \]

**MH-Neg:** By calculating the evolution of ionization fronts during the Epoch of Reionization, Ferrara & Loeb (2013) find that the shallower potential of low mass halos allows rapid ionization of the interstellar medium due to the decreased rate of recombinations. In turn, this allows subsequent generations of ionizing photons to escape into the IGM more easily. This model follows works such as Kimm et al. (2017) who allow the escape fraction to scale negatively as a power law with dark matter halo mass,

\[ \log_{10} f_{esc} = \log_{10} f_{esc,low} - \frac{\log_{10} \frac{M_H}{M_{crit,low}}}{\log_{10} \frac{M_H}{M_{crit,high}}} \log_{10} \frac{M_{crit}}{M_{crit,high}}. \]

The fixed points ($M_{low}$, $f_{esc,low}$) and ($M_{high}$, $f_{esc,high}$) control the slope and normalization of the power law. For halos with mass below (above) $M_{low}$ ($M_{high}$), we set the value of $f_{esc}$ to $f_{esc,low}$ ($f_{esc,high}$).

**MH-Pos:** Gnedin et al. (2008) and Wise & Cen (2009) show that heavy amounts of star formation can create ionized channels within star-forming clouds, providing an easy escape route for ionizing photons. Star formation is the largest in high mass galaxies, which tend to live in high mass halos. Hence, for this model, we use a prescription wherein the escape fraction scales as a positive power law with halo mass,

\[ \log_{10} (1 - f_{esc}) = \log_{10} (1 - f_{esc,low}) - \frac{\log_{10} \frac{M_H}{M_{crit,low}}}{\log_{10} \frac{M_H}{M_{crit,high}}} \log_{10} \frac{M_{crit}}{M_{crit,high}} - \log_{10} \frac{1 - f_{esc,low}}{1 - f_{esc,high}}. \]

The calibration constants are defined identically to the MH-Neg model.

**Ejected:** High resolution hydrodynamical simulations show that feedback is critical in destroying star-forming clouds and allowing easy escape for ionizing photons (e.g., Kimm & Cen 2014; Xu et al. 2016; Kimm et al. 2017). Within RSAGE, we capture this by calculating $f_{ej}$, the fraction of baryons that have been ejected from the galaxy compared to the number remaining as hot and cold gas. By setting $f_{esc}$ to scale positively with $f_{ej}$, we hence allow feedback processes to dictate the instantaneous escape fraction,

\[ f_{esc} = \alpha f_{ej} + \beta. \]

We choose a linear function for simplicity with the strength of coupling controlled by $\alpha$ and the zero-point offset given by $\beta$.

**SFR:** In the MH-Pos model, we use the halo mass as a proxy for the star formation activity that creates ionized channels within the galaxy gas cloud. As RSAGE explicitly models the evolution of galaxies, this model allows $f_{esc}$ to scale explicitly with the galaxy star formation rate (SFR) in the form of a logistic curve,

\[ f_{esc} = \frac{\delta}{1 + \exp \left( -\alpha (\log_{10} \text{SFR}) - \beta \right)}. \]

This functional form was chosen as log$_{10}$ SFR can (theoretically) span $[\infty, -\infty]$ aligning itself to the domain of the logistic curve. Furthermore, the logistic curve has range $[0, \delta]$ allowing easy scaling of the maximum $f_{esc}$.
value. Finally, $\alpha$ sets the steepness of the curve and $\beta$ controls the value of $\log_{10}SFR$ that corresponds to $f_{\text{esc}} = \delta/2$.

3.1 Average Escape Fraction

Figure 2 shows $\langle f_{\text{esc}} \rangle_M$, the mean value of $f_{\text{esc}}$ across all galaxies in a stellar mass bin, as a function of stellar mass. Since high mass galaxies live within high mass halos, $\langle f_{\text{esc}} \rangle_M$ scales negatively and positively with stellar mass for the MH-Neg and MH-Pos models respectively. We find a small redshift evolution in $\langle f_{\text{esc}} \rangle_M$ at low stellar mass for these two models, resulting from the scatter in the stellar mass-halo mass relationship (see Figure 3 of Mutch et al. 2016).

Since feedback effects are able to eject baryons more easily within low mass ($M_\text{low} < 10^7 M_\odot$) galaxies, $\langle f_{\text{esc}} \rangle_M$ scales negatively with stellar mass for the Ejected model. As more massive galaxies tend to have more star formation activity, the SFR model scales positively with stellar mass.

As redshift decreases, the star formation rate of our simulated galaxies at fixed stellar mass drops over time, in agreement with observations and theory (e.g., Sparre et al. 2015; Santini et al. 2017). As the ejection of baryonic material is heavily driven through supernovae activity, a drop in the star formation rate will correspond to less supernovae, allowing galaxies to retain more of their baryonic material. These two phenomena, a decrease in the ejection of baryons and star formation rate, manifests in our models as $\langle f_{\text{esc}} \rangle_M$ decreasing over time for the Ejected and SFR models respectively.

3.2 Ionizing Emissivity and Optical Depth

The left panel of Figure 3 compares the evolution of the ionizing emissivity for each model with the inferred estimates of Bouwens et al. (2015). For all models, the general shape and values of the ionizing emissivity match well with observational estimates, an outcome of the free parameters (as shown in Table 1) used for each model. We emphasise that these parameters were chosen to ensure that the more tightly constrained lower redshift ($z = 6-8$) estimates of Bouwens et al. (2015) were matched closely.

For the majority of our results and calibrations, there is a distinct difference between the $f_{\text{esc}}$ models that scale negatively with stellar mass (MH-Neg and Ejected), and those that scale positively with stellar mass (MH-Pos and SFR). This distinction is highlighted by the ionizing emissivity in the left panel of Figure 3 whose evolution is primarily driven by the growth of the stellar mass function. At early times (redshift $z > 10$), the stellar mass budget is dominated by low mass galaxies. Hence, the MH-Neg and Ejected models will have the largest values of $f_{\text{esc}}$ and thus ionizing emissivity. Over time, massive galaxies become more numerous, shifting the stellar mass budget towards the high mass end. This results in the $f_{\text{esc}}$ values of the MH-Pos and SFR models growing quickly leading to a rapid evolution in the ionizing emissivity. Eventually, at redshift $z \approx 7.5$, the rapid growth in $f_{\text{esc}}$ allows...
Figure 2. Mean escape fraction within each stellar mass bin for each of the $f_{\text{esc}}$ models. Calibration parameters (Table 1) are chosen to match the inferred estimates of the ionizing emissivity from Bouwens et al. (2015) and measurements of the Thomson optical depth from Planck Collaboration et al. (2018).

Figure 3. Left: Ionizing emissivity for each of the $f_{\text{esc}}$ models. The shaded contours show the derived 68% and 95% confidence intervals for the ionizing emissivity inferred using the Thomson optical depth, quasar absorption spectra and the prevalence of Ly$\alpha$ emission in $z = 7$-8 galaxies (Bouwens et al. 2015, Table 2). Right: Thomson optical depth with the 68% confidence interval measurements of Planck Collaboration et al. (2018) shown as the shaded region.
the ionizing emissivity of the MH-Pos and SFR models to surpass all others. Finally, we see that the ionizing emissivity of the Constant model remains firmly in the middle of the pack throughout all of reionization, a result of its $f_{esc}$ values not scaling with stellar mass.

We show the evolution of the Thomson optical depth $\tau$ for each model in the right panel of Figure 3 with the measured values of Planck Collaboration et al. (2018) shown as the shaded region. All models fall comfortably within the observational constraints, a result of calibrating the models to match the Bouwens et al. (2015) ionizing emissivity which used the optical depth as a key constraint. Interestingly, we do not find differences between the models depending upon whether $f_{esc}$ scales positively or negatively with stellar mass. This hints that an integrated property such as $\tau$ cannot accurately distinguish between different $f_{esc}$ models. We explore this conclusion in Section 4.

4 REIONIZATION HISTORY

We now investigate how the different models of $f_{esc}$ affect the global evolution of ionized hydrogen during the Epoch of Reionization. Figure 4 shows the evolution of the mass averaged neutral hydrogen fraction, $\langle \chi_{\text{HI}} \rangle$. We find that $\langle \chi_{\text{HI}} \rangle$ evolves similarly for all models. Reionization begins slowly at redshift $z \approx 11-12$, corresponding to the appearance of the brightest sources ionizing their immediate surroundings. As more galaxies are formed, the ionizing emissivity increases and reionization speeds up, highlighted by $\langle \chi_{\text{HI}} \rangle$ becoming steeper from redshifts $z \approx 10$ to 8. Below redshift $z \approx 8$, reionization begins to slow down as the majority of the simulation box is already ionized.

When comparing the evolution of $\langle \chi_{\text{HI}} \rangle$ for different $f_{esc}$ models, we find a similar story to that told by the ionizing emissivity in the left panel of Figure 3. Due to the higher number of ionizing photons at redshift $z \approx 14$, the MH-Neg and Ejected models begin reionization first, reaching $\langle \chi_{\text{HI}} \rangle = 0.99$ at redshift $z = 12.48$ and $z = 12.22$ respectively compared to the redshift $z = 11.76$ for both the MH-Pos and SFR models. However, despite the MH-Neg and Ejected models starting reionization earliest, they do not finish first. Rather, the MH-Pos and SFR models reionize the universe the quickest and by redshift $z \approx 8$ these two models outpace all others and finish reionization sooner. This echoes the results of the previous Section where we found that the ionizing emissivity of the MH-Pos and SFR models grow the quickest. Once again, we see that the Constant model divides these two regimes.

This difference in reionization speed is summarized in Table 2 where we list the duration $\Delta z (\Delta t)$ of reionization for each model. We find that despite the MH-Neg and Ejected models starting their reionization of the universe first, they have a slower, more extended reionization history compared to the other models. Indeed, the rapid ionizing emissivity evolution in the MH-Pos and SFR models results in a quick Epoch of Reionization. This highlights that, whilst a deficiency of ionizing photons at very early times (redshift $z \approx 14$) leads to a delayed start of reionization, the overall duration of reionization is heavily controlled by the growth of the ionizing emissivity.

The core motivation of this work is to investigate the possibility of distinguishing between different physically motivated models of $f_{esc}$. From Table 2, we find that an $f_{esc}$ model that scales negatively with stellar mass (Ejected) takes $\approx 80$ Myr longer to complete reionization than a model that scales positively with stellar mass (SFR). This story remains the same regardless of the exact definition of ‘duration’ used. Using another common definition of $\Delta z = z_{90\%} - z_{1\%}$ (e.g., Zahn et al. 2012; George et al. 2015) we again find that the SFR model finishes reionization $\approx 80$ Myr earlier than all other models. To check the robustness of this difference in duration, we must consider how an uncertainty in $\tau$ affects our result. We focus on the Ejected model and adjust the free parameter $\alpha$ from 0.30 to 0.45, increasing the value of $\tau$ from 0.054 to 0.061. This recalibration results in a duration of reionization of 391.8 Myr, below the fiducial Constant

5 Here we use the definition of “duration” being the time between $\langle \chi_{\text{HI}} \rangle = 0.90$ ($z_{90\%}$) and $\langle \chi_{\text{HI}} \rangle = 0.01$ ($z_{1\%}$).

6 $\tau = 0.061$ corresponds to the largest $\tau$ value that remains consistent with Planck Collaboration et al. (2018).
model. Hence, with the current uncertainty in $\tau$, the duration of reionization could not differentiate between a Constant $f_{\text{esc}}$ model and one that scales positively with stellar mass (e.g., the SFR model) and has a higher value of $\tau$. We conclude that, with the current uncertainty in $\tau$, the duration of reionization cannot be used alone to differentiate between the different $f_{\text{esc}}$ models.

5 THE TOPOLOGY OF REIONIZATION

From Section 4, we found that an integrated property, such as the optical depth, could not differentiate between the $f_{\text{esc}}$ models. In this Section, we analyse the topology of ionized regions during Reionization. Specifically, we first investigate how the spatial topology of the ionized hydrogen differs between each model. We then quantify these differences using the $21$cm power spectrum and comment on the possibility of the upcoming Square Kilometre Array (SKA) distinguishing between the models.

Spatial Slices Through the Ionization Field

To investigate differences in the spatial topology of ionized hydrogen, in Figure 5 we show one grid cell ($0.39h^{-1}$Mpc) slices through the ionization field for each $f_{\text{esc}}$ model at fixed global neutral hydrogen fractions. We remind the reader that from Figure 1, we have orders of magnitude more low mass ($M_{\star} < 10^8 M_{\odot}$) galaxies compared to high mass ($M_{\star} > 10^9 M_{\odot}$) ones. Due to the relatively low star formation rate of these low mass galaxies, they will produce fewer ionizing photons. Hence for all models, we expect a large number of low powered ionizing sources in conjunction with a handful of massive objects that emit a large number of ionizing photons. This is evident in the Constant model where we have numerous small ionized regions scattered throughout the simulation box alongside a handful of large, extended ionized regions.

For the other models, we must consider how $f_{\text{esc}}$ scales with galaxy stellar mass (Figure 2). For the MH-Neg and Ejected models, $f_{\text{esc}}$ is largest for low mass galaxies. Hence, compared to the Constant model at fixed neutral hydrogen fraction, the number of small ionized regions increases whilst the number of large ionized regions decreases. We quantify this in Table 3 where we show the mean size of ionized regions for the models. Due to the higher number of small ionized regions, the MH-Neg and Ejected models have a smaller mean size compared to the constant model: $11.85h^{-1}$Mpc and $11.79h^{-1}$Mpc compared to $13.93h^{-1}$Mpc at $\langle \chi_{HI} \rangle = 0.25$. Conversely for the MH-Pos and SFR models, $f_{\text{esc}}$ scales positively with stellar mass and this reasoning is reversed; the number of small ionized regions is suppressed whilst the number of large ionized regions is enhanced. This is shown again in Table 3 where the mean size of ionized regions is larger for MH-Pos and SFR models compared to the Constant model: $17.23h^{-1}$Mpc and $18.58h^{-1}$Mpc compared to $13.93h^{-1}$Mpc at $\langle \chi_{HI} \rangle = 0.25$.

7 We compare at fixed neutral hydrogen fractions to ensure we are comparing the same amount of ionization.

21cm Power Spectrum

To observationally map the size distribution of the ionization field, one common technique is to use the $21$cm hydrogen emission line. This signal is extremely sensitive to the presence of neutral hydrogen, providing the perfect tool for constraining the history, topology and sources of reionization. In the remainder of this Section, we focus on the signal’s ability to differentiate between the topologies of the $f_{\text{esc}}$ models.

The $21$cm differential brightness temperature depends on fluctuations in both the ionization and dark matter density fields and is calculated for each cell in the simulation box as \citep{Iliev2012},

$$\delta T_b (x, z) = T_0 (z) \chi_{HI} (x, z) \delta (x, z) \text{ mK},$$

(12)

with

$$T_0 (z) = 28.5 \left( \frac{1+z}{10} \right)^{1/2} \left( \frac{\Omega_m h^2}{0.023} \right),$$

(13)

where $\chi_{HI} (x, z)$ is the neutral hydrogen fraction within each grid cell, $\delta (x, z)$ is the dark matter overdensity defined as $\delta = \rho/\rho_c$ with density $\rho$, $h$ is the Hubble parameter and $\Omega_m$ and $\Omega_b$ denote the critical cosmological matter and baryonic densities, respectively. To calculate the dimensional $21$cm power spectrum, $\Delta^2_h (k, z)$, we define $\Delta T_b (k, z)$ as the Fourier transform of Equation 12 with $k = (k_x, k_y, k_z)$ denoting the 3-dimensional wavenumber,

$$\Delta^2_h (k, z) = 4\pi k^3 \langle \Delta T_b (k, z) \Delta T_b (-k, z) \rangle \text{ mK}^2,$$

(14)

where $\langle \rangle$ denotes the spherically averaged value and we use the \texttt{numpy} Python package \citep{Oliphant2006} to compute the Fourier transform which dictates the pre-factor value of $4\pi k^3$. Due to the numerical resolution of our simulations and its impact on the power spectrum, we limit our analysis to scales $k < 4.0h$ Mpc$^{-1}$.

We first discuss the general evolution and features of the $21$cm power spectrum. In Figure 6 we show the $21$cm power spectrum at fixed neutral hydrogen fractions. To better understand the full redshift evolution of the spectrum, its evolution at specific scales and the topological
Figure 5. Slices through the ionization field for each $f_{esc}$ model (columns) at various fixed global neutral hydrogen fractions (rows). Slices are one grid cell thick (0.39h^{-1}Mpc). The colorbar shows the local ionization fraction within each grid cell with black corresponding completely neutral and white denoting (almost) complete ionization. For the models that scale positively (negatively) with stellar mass we have a low (high) number of large (small) ionized regions scattered throughout the box.

Differences between models, we also show the large scale power as a function of small scale power (hereafter called 'scale space') in Figure 7. Here we define 'large scale' as $k = 0.3h$Mpc$^{-1}$ and 'small scale' as $k = 2.0h$Mpc$^{-1}$.

At the beginning of reionization, when the universe is mostly neutral, the variance in $\delta T_b$ (and hence 21cm power) is driven by dark matter fluctuations, causing the 21cm power to follow the underlying density distribution. As the first small ionized regions begin to appear, all models show an increase in small scale power. Furthermore, Lidz et al. (2008) highlights that this period also corresponds to an ‘equilibration’ phase where overdense and underdense regions have similar brightness temperatures. As a result, this equilibration phase also results in a decrease in large scale power from the start of our simulation to $\langle \chi_{HI} \rangle = 0.90$. This is shown in Figure 7 where we see an increase in small scale power at the expense of large scale power.

As reionization progresses from $\langle \chi_{HI} \rangle = 0.90$ to $\langle \chi_{HI} \rangle = 0.50$, small, isolated ionized regions grow and eventually begin to overlap, reducing small scale power whilst boosting it on large scales. Finally, as reionization passes its midpoint, the majority of the simulation cells. Consequently, beyond $\langle \chi_{HI} \rangle = 0.50$, the 21cm brightness temperature and the resulting power decreases on all scales. This is highlighted in Figure 7 where the turning point for all models lies close to $\langle \chi_{HI} \rangle = 0.50$.

We now comment on the differences in the 21cm power spectra between the $f_{esc}$ models. Since reionization begins at different times for each model (Table 2), the redshift, and hence dark matter density, at $\langle \chi_{HI} \rangle = 0.90$ is different. As mentioned above, the 21cm power during the
Constraining \(f_{\text{esc}}\) with SKA

Figure 6. 21cm Power Spectra for all \(f_{\text{esc}}\) models at fixed neutral hydrogen fractions. Due to the resolution of our simulation, we limit analysis to wavenumbers below \(k < 4.0h\text{Mpc}^{-1}\), shown as the vertical dotted line.

Figure 7. Evolution of 21cm large scale \((k = 0.3h\text{Mpc}^{-1})\) power as a function small scale \((k = 2.0h\text{Mpc}^{-1})\) power. The global neutral fractions marked correspond to the full spectra shown in Figure 6. The thin black dashed line denotes the one-to-one line; below (above) this line we are small (large) scale dominated.

Beginning of reionization is dominated by fluctuations in the dark matter density field. Furthermore, as the MH-Neg and Ejected models reach \(\langle \chi_{\text{HI}} \rangle = 0.90\) at the highest redshift, their dark matter fluctuations are the smallest on large scale and hence they initially have the smallest 21cm power on large scales. By the same logic, the MH-Pos and SFR models have the largest 21cm power on large scales at this time, shown most clearly in the left-most panel of Figure 6.

From Table 3, we saw that, compared to the Constant model, the MH-Neg and Ejected models have smaller ionized regions whereas the MH-Pos and SFR models have larger ionized regions during the intermediate \(\langle \chi_{\text{HI}} \rangle = 0.25, \langle \chi_{\text{HI}} \rangle = 0.50\) and \(\langle \chi_{\text{HI}} \rangle = 0.75\) stages of reionization. This is reflected in the 21cm power spectrum where we find increased small scale power for the MH-Neg and Ejected models and enhanced large scale power for the MH-Pos and SFR models. This is a key finding of our work: allowing \(f_{\text{esc}}\) to scale negatively (positively) with stellar mass increases power on small (large) scales.

Distinguishing Models with SKA

We now focus on the possibility of using the 21cm power spectrum to observationally distinguish between different models of \(f_{\text{esc}}\). Specifically, we focus on the Square Kilometre Array low frequency instrument (SKA1-Low).

In Figure 7, we chose the scales to best elucidate the difference in trajectories for each \(f_{\text{esc}}\) model. Whilst \(k = 0.3h\text{Mpc}^{-1}\) aligns with the large scales probed by the SKA1-Low, we show these trajectories for a more attainable small scale wavenumber \(k = 1.0h\text{Mpc}^{-1}\) in the left panel of Figure 8. At this reduced scale, the models do not show significant differences in small scale power. Nevertheless, the large scale power is still noticeably different between \(f_{\text{esc}}\) models that scale positively and negatively with stellar mass.

From the scale-space trajectories in Figure 8, it is difficult to assess the relative large and small scale power across models at a fixed redshift. This will be critical for upcoming radio telescopes which will target specific redshift windows. To this end, we remove a dimension of

\[\Delta^2_{21}[\text{mK}^2](k = 0.3h\text{Mpc}^{-1})\]

\[\Delta^2_{21}[\text{mK}^2](k = 2.0h\text{Mpc}^{-1})\]
the scale-space trajectories and calculate the slope of the 21cm power spectrum between small and large scales,

\[ m = \frac{\Delta_{21,\text{large}} - \Delta_{21,\text{small}}}{k_{21,\text{large}} - k_{21,\text{small}}} \]  

(15)

We show the evolution of the 21cm slope in the right panel of Figure 8. Initially as small scale power increases at the expense of large scale power, the slope of the spectrum increases for all models. Then, as this equilibration phase ends and ionized regions begin to grow, large scale power grows quickly, as shown by the scale space trajectories in the left panel of Figure 8, leading to a decline in the slope. After each model reaches the midpoint of reionization, the slope continues to decrease but at a slower rate, mirroring the extended second half of reionization we saw in Figure 4. Finally, we see that the large scale power never exceeds the small scale power in the Ejected model; hence the power spectrum slope is never negative for this model.

To make accurate conclusions regarding the SKA1-Low’s ability to differentiate between the models, we must account for the observational uncertainty associated with the instrument. Using the V4A\(^8\) array configuration for the SKA1-Low and matching the system temperature and effective collecting area as a function of frequency to the SKA1 System Baseline Design document\(^9\), we calculate the 21cm power spectrum sensitivity assuming a 10MHz bandwidth, an integration time of 200 hours\(^10\) and a redshift window of \(z = 8-10\). At wavenumbers \(k = 0.3\)hMpc\(^{-1}\) and \(k = 1.0\)hMpc\(^{-1}\), we find an uncertainty of \(1.15 \times 10^{-2}\)mK\(^2\) and \(1.37\)mK\(^2\) respectively. Propagating these uncertainties in Equation 15, we show the SKA1-Low 21cm power spectrum slope uncertainty in the right panel of Figure 8 as shaded regions. We find that above redshift \(z \approx 8.5\) and below redshift \(z \approx 7.5\) the models are indistinguishable. For \(z > 8.5\), reionization has only just begun and the difference in topology has not fully manifested. Conversely, for \(z < 7.5\), reionization is reaching its conclusion where the ionized regions merge and hide topological differences.

Finally, we discuss how an uncertainty in the Planck Collaboration et al. (2018) measurement of \(\tau\) affects our result. Similar to the reionization history, we investigate this by recalibrating our models to produce the largest value of \(\tau\) that remains in agreement with Planck Collaboration et al. (2018) (i.e., \(\tau = 0.061\)) and show the scale-dependent evolution of the 21cm power spectrum as thin lines in Figure 8. Immediately we see that even with an adjusted value of \(\tau\), the Ejected model never has more large scale power than small scale. This provides a ‘smoking gun’ to rule out \(f_{esc}\) models that scale negatively with stellar mass. We find that the increased \(\tau\) Constant model is observationally indistinguishable from the fiducial SFR model. However, we also see that the shape of the scale-space trajectories and \(m\) remains largely unchanged for the increased \(\tau\) models. Hence, one method to observationally distinguish between models of \(f_{esc}\) with an uncertain value of \(\tau\) is to measure the maximum or minimum values of \(m\). This will require multiple redshift measurements of the 21cm power spectrum to determine where the maxima/minima lie. Furthermore, to ensure that the models do not have overlapping observational uncertainties at these points, the integration time must be increased to approximately 800 hours.

6 DISCUSSION

For all our models, we did not account for the contribution of quasars to the ionizing emissivity. In theory, the hard ionizing radiation of quasars would create large ionized regions enhancing 21cm power on large scales. Datta et al. (2012) find that the size of such regions is comparable to the regions surrounding clustered stellar sources, hinting that the inclusion of quasar radiation could impact the scale-space trajectories (Figure 7 and the left panel of Figure 8) by shifting all paths towards the MPHs and SFR models. However, the exact contribution of quasars to the ionizing photon budget remains a contentious topic (e.g., Kollmeier et al. 2014; Madau 2017; Qin et al. 2017; Parsa et al. 2018).

A key aspect of reionization simulations is the ability to appropriately model low mass objects during the earliest stages of the Universe. In our work, we do not expect the limited mass resolution of Kali (resolving halos of mass \(4 \times 10^6 M_\odot\)) to significantly affect our results. Due to radiative feedback, the low mass galaxies hosted by halos smaller than the resolution limit would only contribute to the ionizing photon budget during the early stages (redshift \(z > 11\)) of reionization. Furthermore, from Figure 8, the scale-space trajectories during this period are observationally indistinguishable.

The functional forms of \(f_{esc}\) for the Ejected and SFR models were chosen to capture the underlying mechanism that links \(f_{esc}\) to galaxy-scale processes, as highlighted by authors such as Gnedin (2008), Wise & Cen (2009), Kimm & Cen (2014), Kimm et al. (2017) and Trebitsch et al. (2017). However, we do acknowledge that we chose such functions (i.e., linear and logistic) primarily for their simplicity. Whilst selecting different functional forms may produce slightly different results, we stress that the role of these functions were to provide \(f_{esc}\) models that scale negatively/positively with stellar mass. Importantly, the RSAGE model is constructed to allow any arbitrary form of \(f_{esc}\), providing a powerful avenue for exploring more complex functional forms (e.g., Paardekooper et al. 2015) as our ability to model and observe \(f_{esc}\) becomes more nuanced and extensive.

7 CONCLUSION

In this work we have introduced RSAGE, a new open source,\(^11\) galaxy evolution model which self-consistently accounts for feedback effects associated with the Epoch of Reionization. Motivated by work highlighting the importance of galaxy-scale feedback on the instantaneous value of \(f_{esc}\) (e.g., Paardekooper et al. 2015; Kimm et al.\(^8\))
We find adopting an $f_{esc}$ model that scales negatively with stellar mass causes reionization to start early due to the presence of many low mass galaxies. However, as galaxies grow more massive over time, the mass-averaged value of $f_{esc}$ drops for these models leading to a slow, extended Epoch of Reionization. As a result, models that scale positively with stellar mass complete reionization sooner, despite starting much later, due to the comparatively rapid growth in ionizing emissivity. Regardless of these different reionization histories, we find that measurements of integrated quantities, such as the optical depth by Planck Collaboration et al. (2018), can not distinguish between different $f_{esc}$ models.

However, the different $f_{esc}$ models leave distinct signatures in the ionization topology. Due to the high number of low mass galaxies, an $f_{esc}$ model that scales negatively with stellar mass will have many galaxies that ionize their immediate surroundings. This leads to a high number of small ionized regions scattered throughout the simulation box. Conversely, for an $f_{esc}$ model that scales positively with stellar mass, we find (at a fixed global neutral hydrogen fraction) a handful of very large ionized regions. The constant $f_{esc}$ case divides these two regimes.

These differences in the ionization topologies manifest in the power spectra of the 21cm signal. Since the abundances of the smallest and largest ionized regions represent the key differences in the different $f_{esc}$ models, we have plotted the evolution of the large scale power as a function of the small scale power. We find that our adopted $f_{esc}$ models have distinctly different trajectories through this scale space: large scale power never exceeds small scale power in $f_{esc}$ models scaling negatively with stellar mass, while it surpasses small scale power for $(\chi_{HI}) < 0.5$ in $f_{esc}$ models scaling positively with stellar mass.

With the relation between the large and small scale power being the key distinction criterion between our $f_{esc}$ models, we derive the redshift evolution of the corresponding slope of the 21cm power spectra, $(\Delta_{21,\text{large}} - \Delta_{21,\text{small}}) / (k_{21,\text{large}} - k_{21,\text{small}})$. This slope reaches the lowest (highest) values for $f_{esc}$ models that scale positively (negatively) with stellar mass. These $f_{esc}$ model dependent characteristics, particularly the negative slope for $f_{esc}$ models scaling positively with stellar mass, provide an avenue to distinguish between different $f_{esc}$ dependencies of star-forming galaxies during reionization by means of the evolving 21cm power spectra.

We find that 200h observations with the SKA1-LOW allow us to distinguish between different $f_{esc}$ models with similar optical depth values ($\tau$). For $\tau \approx 0.055$, measurements of the 21cm power spectra between redshifts $z \approx 7.5-8.5$ provide the highest constraining power. However, taking the uncertainties of the optical depth measurements into account, it is crucial to pinpoint the redshifts of the maximum and minimum 21cm power spectrum slope. This requires not only 21cm power spectra measurements for a larger redshift interval $z \approx 7-10$, but also higher accuracy. We find that 800h observations with SKA1-LOW will enable us to detect (1) the amplitude and redshift of the maximum slope and (2) most importantly the sign of the slope. A positive slope throughout reionization will hint at a scenario where the $f_{esc}$ values decrease with the stellar mass of the galaxies, while a negative slope during the overlap phase of reionization will indicate that $f_{esc}$ increases with the stellar mass of galaxies.

In summary, measuring the relation between the large and small scale power of the 21cm power spectrum with
SKA will allow us to derive constraints on the dependency of the escape fraction of ionizing photons on stellar mass, increasing our knowledge on high-redshift galaxy properties critically. Nevertheless, emission line detections of high-redshift galaxies and possibly higher-order statistics such as the 21cm bispectrum may be still required to pin down this property of the sources of reionization.

ACKNOWLEDGEMENTS

We would like to thank Cathryn Trott for providing the baseline distributions and sensitivity of the Square Kilometre Array. We would also like to thank Emma Ryan-Weber for useful discussions.
