Since its first detection in March 2020, there have been more than 2,600 cases and at least 14 deaths that were officially attributed to Coronavirus Disease 2019 (COVID-19), caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), in the Turkish Republic of Northern Cyprus (TRNC). While COVID-19 spread was under control, thanks to the non-pharmaceutical interventions implemented during the early stages of the pandemic, lifting some control measures in the second half of the year resulted in a continuously elevated number of confirmed cases, that still continues today.2

One control measure implemented globally was school closure to reduce social contact between children. The data motivating this implementation was mainly based on past experiences with influenza outbreaks, for which children were the major transmitters. While the SARS-CoV-2 transmission dynamic appears to be different since current accumulating evidence suggests children are not the major driver of COVID-19 spread and are rarely involved in secondary transmission3,4, this was also thought to be due to lower testing and exposure in children, which should be addressed for more reliable conclusions.5 Today, more attention has
been drawn on pediatric transmission due to an increased number of cases and the emergence of new variants of the virus.\(^6,7\) Initial studies conducted early in the pandemic regarded children as the ‘silent spreaders’ of SARS-CoV-2 due to the higher rate of asymptomatic COVID-19 infection in the pediatric population than that reported for adults.\(^4,8\) However, despite data on the asymptomatic spread of SARS-CoV-2, this mode of transmission by children, which may spread the virus for extended periods\(^9\) and can act as a potential source of undetected community transmission, has not yet received enough attention in the literature.\(^4\) This could be especially important for emerged variants of the virus with quicker transmission rates.\(^10\)

The aim of our study was to retrospectively evaluate asymptomatic SARS-CoV-2 exposure among a group of pediatric patients, who were admitted to a university hospital, without any complaint associated with or any history of SARS-CoV-2 infection, in the TRNC after the school closure implementation was lifted (i.e. after September 2020). For our study, serologic testing was preferred as it can detect antibodies from both past and present infections. The results would provide data on pediatric asymptomatic infection rates that may contribute to future studies on the planning of health care policies.

**Material and Methods**

**General characteristics of the TRNC population**

According to the latest data provided by the TRNC Statistical Institution (TSI) in 2011, the total population of TRNC was reported to be 286,257 with 150,483 (52.6%) male and 135,774 (47.4%) female subjects. The numbers of subjects with ages of <19 years, 20-49 years, 50-64 years, 65-84 years and >85 years were 73,517 (25.7%); 150,105 (52.4%); 39,377 (13.8%); 21,435 (7.5%); and 1,823 (0.6%), respectively.\(^11\)

**Ethical approval**

This retrospective study was approved by Near East University (NEU) Scientific Research and Evaluation Ethics Committee (Project No: YDU/2020/86-1226). All patient databases were obtained using the hospital information system after receiving informed consent from the parents. Absence of any past SARS-CoV-2 infection was confirmed by hospital records and interviews with parents.

**Serum samples**

Blood samples collected for routine testing from 80 children who were admitted to Near East University Hospital for routine control or with complaints other than those associated with COVID-19 between September 2020 and January 2021 were included in the study. Centrifuged blood specimens were stored at 4 °C until analysis. Serum samples were then separated and used for enzyme-linked immunosorbent assay (ELISA) for retrospective detection of SARS-CoV-2 IgG antibodies.

**ELISA**

To evaluate IgG production, isolated serum samples were analysed by CE-in \emph{vitro} diagnostic-certified Dia.Pro COVID-19 IgG kit (Diagnostic Bioprobes, Sesto San Giovanni, Italy), following the manufacturer’s guidelines. The kit is involved in detection of antibodies against SARS-CoV-2 nucleocapsid (NC) and spike (S) antigens.

The kit has sensitivity of more than 98% as indicated in the manufacturer’s manual. It was also reported to have specificity and sensitivity rates between 84%-98% and 92%-98%, respectively, by independent studies using samples from symptomatic and asymptomatic SARS-CoV-2 reverse transcription-polymerase chain reaction (RT-PCR)-confirmed patients.\(^12,13\)

**Results**

**Patient characteristics**

A total of 80 children (40 boys and 40 girls) who were admitted to the Near East University Hospital without any symptoms associated with COVID-19 were included in the study.
with SARS-CoV-2 infection were included in our retrospective study. The age of pediatric patients ranged between 2 and 15 years, with an average age of 7.6 ± 4.0 (SD) years.

Among those, 31 (38.5%) were with a pre-diagnosed underlying condition including neurodevelopmental (n=11, 13.8%) and nephro-urological disorders (n=10, 12.5%). While 17 (21.3%) children admitted to the hospital for routine check-up control, the remaining displayed complaints such as gastrointestinal (n=20, %25), dermatologic (n=12, 15%), and genitourinary (n=10, %12.5) symptoms. Among those with complaints, seven (8.8%) were concluded not to be associated with any disease, condition or disorder and the rest were diagnosed with conditions such as infection/inflammation (n=26, 32.5), nephro-urological disorder (n=12, 15%), hematological disorder (n=12, 15%), and neurodevelopmental disorder (n=11, 13.8%) (Table I, supplementary data).

**SARS-CoV-2 IgG seropositivity results**

The seropositivity rate of IgG antibodies in the collected serum samples was investigated by using Dia.Pro anti-SARS-CoV-2 ELISA IgG kit. Analysis of 80 serum samples revealed only one specimen (patient number 51) with IgG seropositivity (1.3%).

**Discussion**

Current literature does not have any data on SARS-CoV-2 seropositivity among asymptomatic children in Northern Cyprus. The aim of our study was to fill this gap in the literature by using blood samples collected from children who were admitted to a university hospital with complaints not associated with COVID-19 and no history of a SARS-CoV-2 infection. The study covered a period of five months after the international flight restrictions and school closure implementations were lifted, during which 1,394 subjects were reported positive out of 182,723 molecular tests performed in the country.

Serologic tests were preferred for our investigation as they can detect antibodies produced during both present and past infections. Such serologic studies would provide data for health-care policies, and on the immune status of children in the region. According to the latest data provided by TSI in 2011, the population younger than 20 years of age constituted 25.7% (n=73,517) of the overall (n=286,257) TRNC population.

Our study reported 1.3% IgG seropositivity in the pediatric population. Furthermore, there has not been any multisystem inflammatory syndrome or Kawasaki syndrome cases observed in the pediatric patient population in the hospital during the time that the study was conducted. The only patient with an IgG+ result was a two-year old girl who had a complaint of anal itching and was diagnosed with parasitosis caused by *Enterobius vermicularis*. However further testing, such as a neutralization assay, is required to confirm the data due to cross-reactivity previously suggested between SARS-CoV-2, and parasites.

The asymptomatic seropositivity rate detected in our study is similar to the global seroprevalence previously reported for populations younger than 20 years of age (2.3%; 1.0 – 3.6%). Since children are more likely to be infected at home during widespread school closures, the low seropositivity rate is thought to be due to reduced exposure because of the school closure implementation that was in practice between March-September 2020. On the other hand, considering the asymptomatic infection rate among children that ranged between 15% to 42%, our data also indicates that children in the country are generally susceptible to SARS-CoV-2 infection, and highlights the importance of prevention and control measures for the pediatric population.

In our study, IgM seropositivity rates were not investigated which underestimates the possible impact of early infections on the seropositivity rate reported. While IgM-based tests were more sensitive in the detection of symptomatic than...

PFIC: progressive familial intrahepatic cholestasis

*Three patients had mixed underlying conditions.

†One patient had complaints of both nausea and vomiting.

‡Thirteen patients were diagnosed with more than one disorder/infection.
asymptomatic SARS-CoV-2 infections, this could be due to delayed sampling time as it is difficult to identify the onset of the asymptomatic infection. Furthermore, in a recent study, detection of IgM and IgG antibodies, especially in combination with nucleic acid-based tests and pulmonary computed tomography, was suggested as a preferred method for detection of asymptomatic SARS-CoV-2 infections.

Screening for SARS-CoV-2-specific IgA antibodies can also be considered for future studies since like IgM, IgA production starts and peaks within the first 7 days of infection.

In our study, because of its retrospective nature, it was not possible to collect molecular and/or serological data from other family members and investigate the effects of asymptomatic children on SARS-CoV-2 transmission. Therefore, future community-based studies with the inclusion of subjects of different ages at multiple time points would not only contribute to the relevant literature on the role played by asymptomatic children, but also influence policy decisions during the pandemic in Northern Cyprus.

In addition to the limitations described above, another limitation that prevented us from drawing comprehensive conclusions in our study was the low sample size. Furthermore, since asymptomatic patients are unlikely to be hospitalized, community-based studies are recommended for the estimation of the actual asymptomatic infection rate among the pediatric population in the country.

To conclude, our study reported an asymptomatic SARS-CoV-2 seropositivity rate of 1.3% among children in Northern Cyprus, which can further increase due to the lifting of school closure implementation. Therefore, rapid antigen or RT-PCR tests that may be performed along with serological assays are recommended to continuously monitor SARS-CoV-2 infection among the pediatric population for the control of COVID-19 spread in the country.
