(Dated: to appear in Physical Review B 2006)

We present a viewpoint of the transport process in quantum cascade laser structures in which spatial transport of charge through the structure is a property of coherent quantum-mechanical wavefunctions. In contrast, scattering processes redistribute particles in energy and momentum but do not directly cause spatial motion of charge.

I. INTRODUCTION

Unipolar quantum cascade (QC) laser devices are intraband semiconductor devices in which the transport processes and optical (intersubband) transitions which give rise to the lasing operation occur only in the conduction band of the semiconductor structure. This marks a departure from previous interband semiconductor lasers. Since the first realization of a QC laser, there has been a proliferation of QC laser designs QC laser structures are composed of a complicated sequence of semiconductor layers with different material compositions and thicknesses. This sequence is repeated tens or hundreds of times giving rise to a periodic structure in the device. Considering the complicated layer composition of these devices, the nature of the charge transport process through these structures is not immediately apparent.

The original concept by Kazarinov and Suris was based on coherent tunneling between neighboring wells. It was soon realized however that scattering plays a crucial role in establishing the nonequilibrium carrier distribution, in particular for the depopulation of the lower laser level. Thus almost all simulations of transport in QC structures assume a semiclassical model, in which the transport occurs through scattering transitions between energy eigenstates (Wannier-Stark hopping). In such an approach only diagonal elements of the density matrix (populations or distribution functions) in the Wannier-Stark basis are used, and offdiagonal elements are neglected (hence, the term semiclassical). Ref. 2 briefly considered a more fully quantum-mechanical extension to this semiclassical approach by also including offdiagonal elements (coherences) of the density matrix in the calculation. This study concluded that quantum-mechanical coherences were of limited importance to the transport properties. However, coherent effects were observed experimentally for the electron transfer from the injector to the upper laser level in QC structures.

The importance of coherent effects has also recently been stressed by Ref. 10, where a simplified calculation scheme is proposed.

The concept that scattering transitions propel the current through heterostructure systems conflicts with the standard description of transport in bulk structures, where complex Bloch functions carry the current, while scattering redistributes the carriers in momentum space but does not change their spatial positions. We will show that a similar description also holds in quantum cascade lasers where the current is carried by quantum-mechanical wavepackets, and the scattering only acts locally redistributing carriers in energy or momentum.

II. THE MODEL

The quantum-mechanical transport theory we use here is based on nonequilibrium Green’s functions which allow for a consistent combination of scattering and coherent evolution. Quantum-mechanical coherences are represented by offdiagonal elements of the $G^< (E)$ correlation function, which is related to the density matrix $\rho_{\alpha \beta} = \int dE G^<_{\alpha \beta, k} (E)/2\pi i$. The theory is formulated with basis states $\Psi_{\alpha k} (r, z) = (e^{ikr}/\sqrt{A}) \psi_{\alpha} (z)$. Here $\psi_{\alpha} (z)$ is the envelope function in the growth direction $z$. The wavevector $k$ and the spatial coordinate $r$ are two-dimensional vectors in the plane of each semiconductor layer (with normalization area $A$), taking fully into account the three-dimensional nature of the structure.

We divide the total Hamiltonian as $\hat{H} = \hat{H}_o + \hat{H}_{\text{scatt}}$. The free Hamiltonian $\hat{H}_o$ contains the kinetic energy and applied voltage, together with the electron-electron interaction in a mean field approximation. It is diagonal in $k$, while $\hat{H}_{\text{scatt}}$ describes scattering interactions $k \rightarrow k'$. Here we explicitly take into account acoustic phonon and longitudinal optical phonon, impurity, and interface roughness scattering processes. $\hat{H}_{\text{scatt}}$ is treated perturbatively using self-energies in the self-consistent Born approximation. For example, for impurity scattering, the self-energy has the form

$$\Sigma^{<, \text{imp}}_{\alpha \alpha', k} (E) = \sum_{\beta \beta', q} (V^{\text{imp}}_{\alpha \beta} (q)V^{\text{imp}}_{\beta' \alpha} (-q)) G^<_{\beta \beta', k - q} (E) \quad (1)$$

where $V^{\text{imp}}$ represents the impurity scattering potential. In the following, we consider both the complete form of Eq. (1) with nondiagonal self-energies (ND), as well as approximations summarized in Table 1. In each case, the system of equations for the Green’s functions and self-energies is solved self-consistently, which is an extensive numerical task. This results...
charge and V shown that both coherent evolution (conception that current flow occurs by a combination of nondiagonal self-energies. NDL restricts the scattering matrix elements directly for the respective basis functions. 

**III. VANISHING OF $J_{\text{scatt}}$**

In Ref. 13, we neglected the offdiagonal elements of the self-energies, i.e., only terms with $\alpha = \alpha'$ and $\beta = \beta'$ (diagonal self-energy, DG in Table I) were included in Eq. (1). In this restricted theory, we found $J_0$ and $J_{\text{scatt}}$ to be similar in magnitude. In contrast, using the more rigorous and complete formulation of the theory reported here, where all self-energy terms are included (nondiagonal self-energies, ND), we find that $J_{\text{scatt}} \approx 0$. This result is basis invariant if the complete nondiagonal self-energies (ND) are used, as we checked this explicitly (numerically) for all three types of basis sets. Hence the total current density is given by $J_0$.

The same result has recently been analytically demonstrated by Lake and Pandey. In the position eigenstate basis, where the matrix $z_{\alpha\beta}$ is diagonal, the expression (16) for $J_{\text{scatt}}$ of Ref. 13 becomes

$$J_{\text{scatt}} = \frac{2e}{\hbar V} \sum_{\mathbf{k}} \int \frac{dE}{2\pi} \sum_{\alpha \beta} z_{\alpha\beta} \left( G^{<}_{\alpha\beta, \mathbf{k}} \Sigma^{\text{adv}}_{\alpha\beta, \mathbf{k}} + \Sigma^{\text{ret}}_{\alpha\beta, \mathbf{k}} G^{<}_{\beta\alpha, \mathbf{k}} \right).$$

Now the term in brackets corresponds to the right-hand side of the continuity equation as given in Eq. (57) of Ref. 13, which has to vanish. See also Section 2.4 of Ref. 13.

A second line of argument runs as follows: For microscopic scattering potentials which only depend on $\mathbf{r}$ (but not on momentum $\mathbf{p}$), the commutator $[\hat{H}_{\text{scatt}}, \hat{z}]$ vanishes and hence $J_{\text{scatt}} = 0$ by its definition. Thus $J_{\text{scatt}} = 0$ holds for a wider class of scattering processes, including electron-electron scattering, than studied numerically here. These analytic arguments demonstrate that the previous observation of a finite $J_{\text{scatt}}$ in Ref. 13 is an unphysical result caused by the DG-approximation in the self-energies for a nonlocal basis of Wannier functions.
IV. SPATIALLY-LOCAL SCATTERING IN $J_o$

Although $J_{\text{scatt}}$ vanishes this does not imply that scattering processes are absent from the transport process. These processes do not appear explicitly in Eq. (2) but they act implicitly in determining $G^<(E)$, and hence in driving the current $J_o$. We now investigate the role played by scattering processes in determining $J_o$. In particular, we seek to establish if each scattering event results in a spatial displacement of charge, or if a scattering process acts locally resulting in energy redistribution but with no accompanying spatial transport.

This issue can be conveniently addressed within the basis of position eigenstates. In contrast to the Wannier wavefunctions [Fig. 1(a)], these position eigenfunctions are localized to within a single well layer in the structure [see Fig. 1(b)] and the scattering potential matrix elements $\langle \alpha | V | \beta \rangle$ are significantly smaller for $\alpha \neq \beta$ than for $\alpha = \beta$. We therefore compare the effect of excluding or including certain scattering potential terms in the self-energies, see Table I.

Fig. 2 shows that $J^{\text{NDL}}$ and $J^{\text{ND}}$ are almost identical for both samples. This indicates that the potential terms $(V_{\alpha \alpha}, V_{\alpha \alpha})$ and $(V_{\alpha \alpha}, V_{\beta \beta})$ constitute the main contribution to the self-energies in the calculation of $J_o^{\text{ND}}$, our most rigorous formulation of the current. These scattering terms involve only purely local (in space) transitions, as $V_{\alpha \alpha}$ represents a transition matrix element between states with the same envelope function $\psi_\alpha(z)$, i.e., localized to the same well. This implies that the scattering processes act only locally in space. They do not cause spatial displacement of charge, but act only to redistribute momentum $k$ and energy.

A key point of our argument was the use of the position eigenstate basis which enabled us to demonstrate that the dominant scattering processes in $J_o$ act locally and therefore do not contribute to the spatial transport of charge by $J_o$. This result is not evident if we work in another basis, e.g., Wannier or Wannier-Stark, where the wavefunctions are far more delocalized and off-diagonal matrix elements $V_{\alpha \beta}$ play a significant role. Nevertheless, physical mechanisms, such as the nature of transport, must be basis invariant. Indeed, as long as the full self-energies are taken into account, the expression for the currents $J_0$ and $J_{\text{scatt}}$ are invariant under basis transformations. This demonstrates that the same result is recovered even in the case of a delocalized basis, where the interplay of all types of matrix elements in Table I reproduces the locality of scattering transitions. In contrast, the neglect of certain matrix element combinations (such as the DG-approximation) generates spurious nonlocal scattering transition in a delocalized basis.

V. TRANSPORT OF $J_o$ BY COHERENT WAVE FUNCTIONS

As we have just seen, the scattering processes which contribute to $J_o$ have a purely local effect which does not spatially displace carriers. Hence, we conclude that the transport of charge by $J_o$ through the structure must arise as a property of the quantum-mechanical wavefunction. We can obtain a more concrete visualization of this transport mechanism by resolving $J_o$ in energy and space:

$$J_o(E, z) = \frac{e}{\pi |A|} \sum_{\alpha, \beta, k} \text{Re} \left\{ \frac{-\hbar}{m(z)} \frac{\partial \psi_\beta(z)}{\partial z} G^{\langle\langle}_{\beta \alpha, k}(E) \right\} .$$

The lower panel of Fig. 3 shows that the current $J_o(E, z)$ flows at different energies in different spatial regions of the structures. To satisfy the equation of continuity, scattering interactions enable energy transitions which occur locally as discussed above (an example is depicted by the vertical arrow in the figure). Thus, scattering gives rise to a redistribution of electrons in energy but does not cause a spatial displacement or spatial transport of charge.

Fig. 4 shows the corresponding result for sample A. Here the current density is restricted to a narrow energy range while crossing the thick barrier (around $z = -2$ nm) between the injector and the active region, thus providing the desired selective feeding of the upper laser level. This demonstrates how this representation allows for a detailed insight into the microscopic operation of
localized in the wells as charge tends to accumulate in the coherent wave packet. The peaks in density the distance over which charge is transported by a single length scale gives a measure of the coherence length, i.e., states

Thus, the energy-resolved current is carried by wave functions \( \phi_{\mathbf{k}}(z) \) can be viewed as generalized states for a nonequilibrium system, where the drive by bias and scattering processes compensate.

The currents associated with these wave packets can differ significantly: The state at -29.2 meV (corresponding to the upper laser level) has only a small current, but a high occupation. In contrast, the state at \( E = -41.3 \) meV (lower laser level) exhibits a strong current to the right, effectively moving electrons away from the lasing transition which occurs vertically between these states. There are also states exhibiting local current flow to the left, e.g., at -22.4 meV. Such considerations may provide new tools for the optimization and design of new laser structures.

The complex states \( \phi_{\mathbf{k}}(z) \) are of particular importance at level crossings. This is demonstrated in Fig. 5 for a simple superlattice at the resonance between the ground state and the first excited state of the neighboring well. Fig. 5(a) depicts the Wannier-Stark states, which are spread over both wells. The first two eigenvalues \( f_{\mathbf{k}}(E) \) for \( \mathbf{k} = 0 \) exhibit a clear peak at the level energies [see Fig. 5(b)] and the corresponding states, carry particles to the right [state 1, Fig. 5(c)] and to the left [state 2, Fig. 5(d)]. However, the occupation of the state 1 is about two orders of magnitude larger thus providing a strong current flux over the barrier.

Our viewpoint of current-carrying coherent wavefunctions differs essentially from the conception that scattering transitions propel the current. This manifests itself in two ways: (i) In a scattering transition picture, the current would stop immediately once the scattering processes stop (\( H_{\text{scatt}} \) drops to zero). However, the oc-
VI. RELATION TO WANNIER-STARK HOPPING MODEL

In the Wannier-Stark hopping model, the current is carried by scattering transitions between Wannier-Stark states and depends only on scattering rates and the populations of these states. The coherences, i.e., offdiagonal elements $\rho_{\alpha k, \beta k}$ (diagonal in $k$ in contrast to scattering transition amplitudes $\phi_{\alpha k}(z)$ of the density matrix, play no role in this model and are neglected. There are two peculiarities in this picture: (i) The Wannier-Stark hopping picture of transport through scattering transitions and our picture of transport by coherent wavepackets each provide the entire current and yet offer such conflicting views of the transport mechanism. (ii) If we examine Eq. (2) expressed in the Wannier-Stark basis, we see that a diagonal density matrix results in zero total current. Thus, coherences are central to the transport process, even in the Wannier-Stark basis, see also Ref. 20.

VII. SUMMARY

We have shown that the entire current through QC structures is carried only by complex, quantum-mechanical wavefunctions as shown, e.g., in the upper panel of Fig. 5. This conclusion follows from two main results: (i) The scattering current $J_{\text{scatt}}$ vanishes, which directly follows from $[H_{\text{scatt}}, \hat{z}] = 0$, if the scattering potentials couple to the spatial coordinate of electron states. (ii) In the position basis, only the diagonal scattering matrix elements $V_{\alpha\alpha}$ are significant in determining the current $J_{\alpha}$, and hence the entire current. Such matrix elements do not induce spatial translation of the electron state within the scattering transition. Thus, the principal scattering events which transfer momentum and/or dissipate energy in the transport process in quantum cascade structures occur only through spatially-local transitions which do not give rise to propagation of charge.

The locality of scattering transitions contrasts with the simple picture of electrons hopping between energy eigenstates due to scattering events, which is a common description in heterostructure systems. On the other hand, our point of view is analogous to bulk transport, where the scattering term in Boltzmann’s equation is local in space, and the entire current is carried by Bloch states.

We thank R. Lake for helpful discussion. This work was supported by Deutsche Forschungsgemeinschaft and the Swedish Research Council.

25 For $\Sigma_{\text{ret}}$ and self-energies for other scattering processes, see Ref. \textsuperscript{13}. Impurity scattering is treated microscopically as in Ref. \textsuperscript{24}. We only treat electron-electron scattering in a mean field approximation, but it has been shown that for intersubband transport, electron-impurity scattering usually dominates over electron-electron scattering, see Callebaut, Kumar, Williams, Hu, and Reno, Appl. Phys. Lett. \textbf{84}, 645 (2004).
26 We use an iterative scheme based on the Broyden method, V. Eyert, J. Comp. Physics \textbf{124}, 271 (1996).
27 As a further check on the calculation, current continuity requires that the integration of Eq. \textsuperscript{18} over energy should result in $J_o(z) = \int dE J_o(z, E) = \text{a constant}$. Numerically, we observe a spatial variation due to the limited number of basis states used in the calculation. Increasing the number of basis states to 8 Wannier states per period (also used in Fig. \textsuperscript{13}) reduces this variation to $< 10\%$.
28 This can also be seen in Eq. (4) of Ref. \textsuperscript{21} or Eq. (9) of Ref. \textsuperscript{22}.
