Radiologic findings of Bing-Neel syndrome, which is an extremely uncommon complication resulting from malignant lymphocyte infiltration into the central nervous system (CNS) in patients with Waldenström’s macroglobulinemia (WM), have been infrequently reported due to extreme rarity of the case. A 75-year-old man with WM presented at a neurology clinic with progressive gait and memory disturbances, and dysarthria of 2 months duration. Cerebrospinal fluid and serum protein electrophoresis and immunofixation electrophoresis showed IgM kappa-type monoclonal gammopathy. Brain magnetic resonance imaging revealed multifocal, hyperintense lesions on T2 weighted-images. Brain diffusion-weighted imaging (DWI) demonstrated hyperintensities in cerebral and cerebellar lesions that appeared isointense on apparent diffusion coefficient maps, which were compatible with vasogenic edema. Although histologic analysis is a confirmative study to prove direct cell infiltration into the brain, brain MRI with DWI may be a good supportive study to diagnose Bing-Neel syndrome.

KEY WORDS : Bing-Neel syndrome · Waldenström’s macroglobulinemia · MRI.

INTRODUCTION

Waldenström’s macroglobulinemia (WM) is a chronic malignant proliferative disorder of lymphoid cells that infiltrates bone marrow and produces IgM monoclonal protein in serum8). In 1936, Bing and Neel3) reported an association between hyperglobulinemia, central nervous system (CNS) symptoms, and brain infiltration comprised of plasma cells and lymphocytes in two patients. Since then, the eponym Bing-Neel syndrome, has been used to define the extremely rare cases of WM with CNS involvement. The mechanism underlying CNS involvement has been explained as direct CNS infiltration of malignant cells; histologic analysis is needed to confirm the direct cell infiltration6). With the recent dramatic advances in radiology, a key evaluation for diagnosis of many CNS diseases has moved from histologic studies to radiologic studies. However, the radiologic findings of CNS involvement in patients with WM have been rarely reported due to the extreme rarity of the combination. A recent case report, in which diffusion weighted image (DWI) findings have been presented, suggested cytotoxic edema representing multiple infarcts as a vascular obstruction mechanism1). Herein, we present a case of Bing-Neel syndrome with DWI findings demonstrating vasogenic edema, and suggest that a brain magnetic resonance imaging (MRI) is a good supportive study in diagnosing the Bing-Neel syndrome.

CASE REPORT

A 75-year-old man presented to our neurology clinic for evaluation of progressive gait and memory disturbances, and dysarthria of 2 months duration. Three years earlier, he was diagnosed with WM by a bone marrow biopsy, which showed lymphoplasmacytic cells with IgM kappa monoclonality. He was treated successfully by immunosuppressive chemotherapy. Two months prior to our evaluation, he began to experience slight dysarthria and memory impairment, which prevented social activities. These symptoms rapidly progressed, and he developed severe dizziness with an ataxic gait three weeks prior to the evaluation. On physical examination, his vital signs were stable, and neither...
lymphadenopathy nor organomegaly was present. On the neurologic examination, he appeared alert, but had slow verbal responses and reduced verbal fluency. His mini-mental status examination score was 24/30 (missing 2 points on orientation, 3 points on recall, and 1 point on his copy of the intersecting pentagon). He had a clinical dementia rating scale of 1.0. The frontal lobe function test was normal. Central-type right facial palsy and right side gaze-evoked nystagmus were observed. The motor and sensory examinations were normal, and there were no pathologic reflexes. On cerebellar function testing, the right upper and lower extremities showed dysmetria. He could not walk without assistance because of tilting to the right side.

The hematologic laboratory values were as follows: hemoglobin, 9.2 g/dL; white blood cell count, 5.9 × 10³/µL with neutrophilia (82.2%); and platelets, 136 × 10³/µL. Blood chemistries, including albumin, was normal. Brain MRI showed hyperintensities involving the capsulostriatal area (anterior thalamus, hypothalamus, anterior midbrain, pons, and medulla oblongata) and the right middle cerebellar peduncle on T2-weighted and fluid attenuated inversion recovery (FLAIR) images (Fig. 1). Post-contrast T1-weighted images revealed focal enhancements in lesions of the right middle cerebellar peduncle (Fig. 1). DWI demonstrated hyperintensities in the cerebral and cerebellar lesions that appeared isointense on apparent diffusion coefficient (ADC) maps (Fig. 2).

His serum IgM level was 1,490 mg/dL (normal range, 50-300 mg/dL), and this was significantly less than the 3,780 mg/dL recorded 3 years previously. His serum β²-microglobulin level was 2.46 mg/dL (normal range, 1-2.4 mg/dL), and this was also lower compared to the level found 3 years previously (4.46 mg/dL). A lumbar puncture (LP), which was performed to investigate possible malignant cell infiltration, revealed a slightly increased cell count and protein level with normal pressure as follows: pressure, 13 cm H₂O; white blood cell count, 81/µL (neutrophils, 22%; lymphocytes, 50%; monocytes, 27%; and eosinophils, 1%); red blood cells, 3/µL; protein, 49 mg/dL; and glucose, 68 mg/dL. The serum microhemagglutination-Treponema pallidum test was negative. The cerebrospinal fluid (CSF) Venereal Disease Research Laboratory (VDRL) test, fungus culture, gram stain and culture, India ink, tuberculosis (Tb) culture, and Tb polymerase chain reaction were all negative, which ruled out an opportunistic infection of the CNS, a common complication of patients with undergoing immunsuppressive treatment. CSF and serum protein electrophoresis and immunofixation electrophoresis showed IgM...
(kappa-type) monoclonal gammopathy. An electrophysiologic study revealed a moderate degree of right median motor neuropathy at the wrist level, compatible with carpal tunnel syndrome, but there was no evidence of peripheral nervous system involvement, typical of WM.

The patient received chemotherapy and intravenous steroid injections as follows: one cycle of chlorambucil (2 mg orally tid per day on days 1-12) and methylprednisolone sodium (60 mg intravenously per day on days 1-5). However, his symptoms slowly worsened, and he died 1 month later. A postmortem pathologic study was not performed at the request of the family.

DISCUSSION

WM is a rare condition, and accounts for only 2% of monoclonal gammapathies, with an age-adjusted incidence of 3.4 per million among males and 1.7 per million among females. Neurologic complications may occur in up to 25% of patients with WM. The most frequent neurologic complication is sensorimotor polyneuropathy. Only extremely rare cases of Bing-Neel syndrome, involving direct CNS infiltration by malignant cells, have been reported.

Because of the rarity of Bing-Neel syndrome, the radiologic features have yet to be elucidated. Some findings have been reported in presumed cases or histopathologically demonstrated cases. Bing-Neel syndrome can be subdivided into diffuse and tumoral forms. In the diffuse infiltrative form, the cerebral lymphoid infiltration predominates in the pons, medulla, periventricular white matter, and leptomeningeal spaces. In the tumoral form, the lesion may be unifocal or multifocal, and is usually located in the deep subcortical hemispheric regions. Nervous system infiltrations appear as contrast-enhancement and/or thickening of meningeal sheaths on computerized tomography or MRI, and may involve the brain parenchyma and cauda equina. In our case, MRI displayed edematous infiltrative lesions in the periventricular white matter, basal ganglia, thalamus, hypothalamus, midbrain, pons, cerebellar peduncle, and cerebellum. Enhancement was observed in lesions of the right middle cerebellar peduncle and basis pontis on MRI, motor examination of our patient revealed normal strength and tone; however, cerebellar symptoms were prominent. The discrepancy between MRI lesions and symptom severity may relate to vasogenic edema. Malignant cell infiltration in the perivascular spaces cause damage to the blood-brain barrier (BBB), resulting in extravasation of plasma, which may present as abnormal signal intensities on MRI. However, neurologic symptoms may not have developed during this stage. The extravasated plasma can damage white matter, inducing a cascade of pathologic events, including cellular proliferation, demyelination, and petechial hemorrhage, leading to delayed cellular degeneration. The enhancing lesion on MRI may be a more significant lesion which directly correlates with clinical symptoms.

Serum hyperviscosity, which is observed in 15% of patients with WM, has been suggested to be the most common pathogenesis of CNS symptoms in WM. The serum hyperviscosity is related to increasing concentrations of IgM paraproteins in serum, which result in red blood cell aggregation and an increased viscosity. The resultant microcirculatory impairment cause clinical symptoms, generally the triad of mucosal bleeding, visual changes, and neurologic symptoms. Neurologic complications vary from mild symptoms (headache, lightheadedness, and fatigue) to severe symptoms (mental confusion, stroke, and focal neurologic deficits). Symptoms usually develop when IgM increases beyond 3 g/L. In the case herein, a low IgM
level (1.49 g/L) on admission and vasogenic edema on DWI were findings incompatible with the hyperviscosity syndrome in WM.

In addition, Bing-Neel syndrome must be distinguished from other cerebral diseases, such as glioblastoma multiforme (a thick irregular ring of tissue around a necrotic core and marked, but inhomogeneous contrast enhancement in most MRIs), multifocal leukoencephalopathy (multifocal oval or round subcortical white matter hyperintensities in the parieto-occipital area by MRI), and primary central nervous system lymphoma (PCL; three-fourths of all PCLs in immunologically-normal patients enhance strongly and homogenously, while AIDS-related PCLs may appear considerably more heterogeneous, with hemorrhagic and necrotic foci by MRI). Clinical findings, including radiologic studies, may help differentiating those CNS diseases.

CONCLUSION

Herein, we report the diffuse form of Bing-Neel syndrome based on accentuated DWI, suggesting vasogenic edema due to malignant cell infiltration in the perivascular space. Although histologic analysis is a confirmative study to verify direct cell infiltration into the brain, a key finding of Bing-Neel syndrome, the DWI findings representing vasogenic edema and infiltrative findings in routine MRI may suggest direct malignant cell infiltration into the CNS as a pathogenic mechanism of CNS symptoms in patients with WM. A brain MRI with DWI may be a good supportive tool to diagnose Bing-Neel syndrome.
