Abstract: The application of CO$_2$ curing on sludge ceramsite may improve its mechanical properties, and then increase the corresponding corrosion resistance. In this study, the influence of CO$_2$-cured sludge ceramsite on the strength and long-term properties of cement concrete is investigated. CO$_2$ curing time ranges from 0 h to 2 d. The cylinder compressive strength and water absorption rate of CO$_2$-cured sludge ceramsite are first determined. Additionally, the flexural and compressive strengths, the chloride permeability and the freeze—thaw damage, as well as the corresponding thermal conductivity of cement concrete, are tested. Furthermore, the corrosion resistance of reinforcement inner-sludge-ceramsite cement concrete is measured. Finally, the scanning electron microscope photos of sludge ceramsite are obtained. Results show that the cylinder compressive strength of CO$_2$-cured sludge ceramsite is 15.1, ~34.2% higher than that of sludge ceramsite. Meanwhile, the water absorption rate of CO$_2$-cured sludge ceramsite is 39.6, ~82.4% higher than that of sludge ceramsite. The compressive strength and the flexural strength of cement concrete with CO$_2$-cured sludge ceramsite are 11.4 and 18.7, ~21.6% and ~31.5% higher than the cement concrete with sludge ceramsite, respectively. The resistance of NaCl freeze—thaw cycles, determined by comparing the mass loss rate and the loss rates of mechanical strengths, is effectively improved by CO$_2$ curing, while the thermal conductivity of cement concrete is decreased by CO$_2$ curing. The corrosion resistance of inner reinforcement is improved by the application of CO$_2$ curing on sludge ceramsite.

Keywords: sludge ceramsite; mechanical properties; compressive strength; water absorption rate; chloride permeability; thermal conductivity

1. Introduction

Ceramsite has been used as a lightweight aggregate in building materials for several years. Ceramsite is a material with a porous structure which shows low strength, thermal conductivity and sound transmission capacity. The addition of ceramsite can be used in the heat preservation and insulation of walls. Moreover, ceramsite usually acts as filling material for acoustic walls [1]. Furthermore, ceramsite can also be applied in road noise reduction due to its porous lightweight performance. Therefore, ceramsite is usually used in pavement concrete [2].

Previously, ceramsite was usually fired from clay. At present, sludge and excavated soil are used for sintering ceramsite [3]. However, toxic and harmful substances, such as heavy metals in sludge and excavated soil, may pollute the environment or damage human health [4]. Ceramsite concrete is light weight, and has an excellent thermal insulation effect, fire resistance and seismic performance. However, due to high water absorption and porosity, ceramsite has a poor working performance, and its strength is lower than that of ordinary concrete [5]. In order to improve the strength of traditional ceramsite and reduce...
the release of toxic and harmful substances from silt ceramsite, some special treatments should be carried out on the sludge or excavated soil.

Carbon neutralization and carbon peak are hot topics in today’s society [6]. Using biological methods (e.g., photosynthesis of plants), it is usually possible to reduce the content of CO$_2$. However, plants cannot efficiently absorb enough CO$_2$ to consume the excess CO$_2$ in the atmosphere. CO$_2$ curing on building materials provides ideas for its absorption [7]. Additionally, prior research pointed out that CO$_2$ curing can effectively improve the mechanical strengths and the durability of cement-based materials [8,9]. Moreover, as described in some journals [10], the drying shrinkage rate of cement-based materials is decreased by CO$_2$ curing.

Zhu et al. [11–14] found that CO$_2$ curing can shorten the setting time of cement paste and improve mechanical strengths. Moreover, the compactness of cement’s hydration products is improved by CO$_2$ curing, thus increasing the durability of cement-based materials [15]. Furthermore, as pointed out in Zhu’s research, CO$_2$ curing on reinforced cement mortar can effectively improve the corresponding corrosion resistance under the external erosion of NaCl freeze–thaw cycles. Additionally, CO$_2$ curing has a more obvious effect on early mechanical properties and shrinkage properties of cement-based materials. Additionally, CO$_2$ curing has been used for strengthening the strength of old mortar in recycled aggregates, thus improving the mechanical strength of recycled cement concrete aggregates. Although much research about CO$_2$-cured cement-based materials has been studied [16,17], little attention is paid to the research of the influence of CO$_2$ curing on lightweight aggregates.

In this paper, the influence of CO$_2$ curing on the cylinder compressive strength and the water absorption rate of sludge ceramsite is investigated. Additionally, the corresponding mechanical strength and anti-chloride permeability are studied. Scanning electron microscopy was carried out to research the effect of CO$_2$ curing on the morphology of sludge ceramsite. This study will effectively use CO$_2$ curing, and simultaneously improve the performance of lightweight aggregates. The success of this study will provide good ideas for improving silt ceramsite and reducing the content of CO$_2$ in the future.

2. Experimental

2.1. Raw Materials

Sludge ceramsite was provided by Anhui Xintian Safety Environment Technology Co., Ltd., Anqing, China. The density of the sludge ceramsite was 412 kg/m$^3$; moreover, the particle diameter ranged from 5 mm to 30 mm. Ceramsite sand with a density of 850 kg/m$^3$ and a fineness modulus of 2.42, manufactured by Zhengzhou Yongtai ceramsite sand Co., Ltd., Zhengzhou, China, was used as a fine aggregate in this study. Ceramsite sand was dried in the blast oven until its weight was constant. The particle size of ceramsite sand ranged from 0.12 mm to 0.4 mm. The particle passing percentage of raw materials was obtained by screening experiment. The measuring process was carried out by the manufacturer. The water absorption rates of sludge ceramsite and ceramsite sand were 16% and 8%, respectively. Ordinary Portland cement, produced by Tianjin Cement Industry Company, Tianjin, China, was applied in this paper. The strength grade and the density of cement were 42.5 MPa and 3.0 g/cm$^3$, respectively. Table 1 shows the main chemical composition of sludge and cement.

| Types     | SiO$_2$ | Al$_2$O$_3$ | Fe$_2$O$_3$ | MgO  | CaO  | SO$_3$ | ZnO  | R$_2$O | Loss on Ignition |

2.2. Sample Preparation

Sludge ceramsite can be produced following these steps.
Firstly, the sludge is dried and ground with loess and bentonite in proportion. Then, the raw materials are mixed into pellets and are dried at (100 ± 5) °C for 2 h. When this step is finished, all mixtures are moved into the high-temperature furnace and pre-heated at 300 °C for 20 min. Finally, the mixtures are calcined at a high temperature of 1100 °C–1200 °C for the last 20 min.

The process for manufacturing the sludge ceramsite cement concrete can be described as follows.

Firstly, the sludge ceramsite is placed on the TH-2 digital display concrete carbonation test box produced by Shanghai Shengshi Huike testing equipment Co., Ltd., Shanghai, China for 0 h, 8 h, 16 h, 24 h, 32 h and 48 h, respectively. The CO₂ concentration for the carbonation experiment is 8%. After carbonation, the cement, sludge ceramsite and ceramsite sand are poured into the UJZ-15 mortar mixer and mixed for 1 min. After that, water is added and mixed for another 2 min. When the mixing of materials is finished, the fresh cement concrete is poured into the mold, forming specimens with sizes of 100 × 100 × 100 mm³, 100 × 100 × 400 mm³ and Φ100 × 50 mm³. The JGJ/T13-2019 [18] is the Chinese standard used for manufacturing the specimens. Table 2 shows the mixing proportions of sludge ceramsite cement concrete. Ceramsite sand and ceramsite are dried in the blast oven until their weights are constant. Therefore, before preparing the specimens, the aggregates are in the dry condition.

Table 2. Mix proportions of ceramsite per one cubic meter (kg).

2.3. Measurement Methods

2.3.1. Basic Physical Properties of Sludge Ceramsite

Sludge ceramsite was firstly immersed in water for more than 2 days until a constant was maintained for the water saturated mass (mt). After that, sludge ceramsite was dried in the blast electrical oven at a temperature of 105 °C to a unified mass.

The cylindrical compressive strength of the sludge ceramsite was determined with a light-weight bearing cylinder by the following process.

The particle size of sludge ceramsite ranges from 10 mm to 20 mm, including the particle size of 10–15 mm, varying from 50% to 70%. Sludge ceramsite with these particles is used for the determination of cylindrical compressive strength. The sample is vibrated for compaction after filling in the pressure cylinder. Then, the load is conducted on the pressure cylinder with a loading rate of 0.3 kN/s~0.5 kN/s. Once the indentation depth reaches 20 mm, the pressing (p₁) is recorded. These experiments are carried out according to the Chinese standard GB/T 17431.2-2010 [19].

2.3.2. Mechanical Strength of Ceramsite Cement Concrete

The compressive and flexural strengths were conducted with specimen sizes of 100 × 100 × 100 mm³ and 100 × 100 × 400 mm³. The loading rates for compressive and flexural strength measurements were 0.45 MPa/s and 0.1 MPa/s, respectively. The measuring process was conducted according to the Chinese standard GBJ81-85 [20].

2.3.3. The Measuring Process of Chloride Ion Permeability and Thermal Conductivity

Specimens with sizes of Φ100 × 50 mm³ and 100 × 100 × 100 mm³ were used for the determination of chloride ion permeability and thermal conductivity. The Chinese stan-
standard GB/T50082-2009 [21] was applied for the measurement of chloride ion permeability. Before the measurement of chloride ion permeability, water saturation treatment with a ZN-BSJ automatic intelligent-vacuum water-filling and fully automatic concrete vacuum water-filling tester machine, provided by Shanghai Shengshi Huike testing equipment Co., Ltd., Shanghai, China, was provided for all specimens. When the specimens were saturated with water, the chloride ion permeability was tested. Specimens with a size of 100 × 100 × 100 mm³ were used for measuring the thermal conductivity with a TC300E portable thermal conductivity tester manufactured by Xi’an Xiaxi Electronic Technology Co., Ltd., Xi’an, China.

2.3.4. The Corrosion Resistance of Reinforced Ceramsite Cement Concrete

The ultrasonic velocity and AC electrical resistivity of the specimens were applied to reflect the corrosion resistance of reinforced ceramsite cement concrete. A Haichuang HC-U91 concrete ultrasonic detector provided by Xi’an Bohui Instrument Co., Ltd., Xi’an, China was used for the measurement of ultrasonic velocity. The probes were pressed on the surface of the specimens. Vaseline was smeared evenly on each size of the specimens. The AC electrical resistance was measured by the TH2810D LCR digital bridge with 104 Hz and 1V. The steel bar was imbedded in the axis position of each specimen, which served as an electrode. Meanwhile, a piece of stainless-steel mesh with an aperture of 4.75 mm and a size of 35 mm × 55 mm served as another electrode. The schematic diagrams of the ultrasonic velocity and the AC electrical resistivity are illustrated in Figures 1 and 2. Equation (1) was used for the calculation of electrical resistivity, where R, A and L are the electrical resistance, the cross-section and the space between the electrodes, respectively. In this study, the space between the electrodes is 20 mm.

\[
\rho = \frac{RA}{L}
\]  

(1)

**Figure 1.** The measurement of ultrasonic velocity.

**Figure 2.** The measurement of the AC electrical resistance.
2.3.5. Microscopic Characterization

The soybean size of ceramsite was taken out from the inner specimens. The selected samples were immersed in absolute ethanol for four days to prevent the hydration of cement. After that, all samples were dried in a vacuum drying oven at 60 °C for four days. The dried samples were sprayed with a gold film before measurement. After that, the SEM (Hitachi Limited., Tokyo, Japan) experiment was carried out.

3. Results and Discussions

3.1. Basic Physical Properties of Sludge Ceramsite

The water absorption rate (WAR) of sludge ceramsite, varying with the increasing CO2 curing time, is shown Figure 3. As illustrated in Figure 3, the WAR of sludge ceramsite decreased with the increasing CO2 curing time. The WAR of sludge ceramsite with CO2 curing for 48 h was 152.4% higher than the sludge ceramsite without CO2 curing. Furthermore, as depicted in Figure 3, the WAR of sludge ceramsite increased by 12.7% with the CO2 curing time increasing from 40 h to 48 h, which indicates that a CO2 curing time of 40 h was the threshold value of CO2 curing times. This is attributed to the fact that the oxide (Al2O3) of sludge ceramsite reacted with the CO2 forming the carbonate, which increased the compactness of ceramsite and decreased the WAR of sludge ceramsite [22]. Additionally, the values of the error bars were less than 0.1, showing low error and high experimental accuracy. Compared with the sludge ceramsite without CO2 curing, the WAR was 17.6, ~60.4% higher than the sludge ceramsite cured by CO2 for 8 h–48 h [23].

![Figure 3. Water absorption rate of sludge ceramsite.](image)

Figure 4 illustrates the cylinder compressive strength of sludge ceramsite. As shown in Figure 4, the cylinder compressive strength of sludge ceramsite increased with the increasing CO2 curing time. When CO2 curing time increased from 0 h to 40 h, the increasing rate of cylinder compressive strength was 18.8%. However, when CO2 curing time increased from 40 h to 48 h, the increasing rate of cylinder compressive strength was 0.44%. This is ascribed to the fact that CO2 curing results in the improved compactness of sludge ceramsite [24]. Therefore, the cylinder compressive strength is improved by CO2 curing time. Compared with the sludge ceramsite without CO2 curing, the cylinder compressive strength was 2.4–18.8% higher than the sludge ceramsite cured by CO2 for 8 h–48 h [23].
Figure 4 illustrates the cylinder compressive strength of sludge ceramsite.

3.2. The Slump of Sludge Ceramsite Cement Concrete

Figure 5 presents the slump of fresh sludge ceramsite cement concrete. The aggregates (sludge ceramsite) were in a saturated-surface dry condition during preparation of the concrete. As observed in Figure 5, the slump of fresh sludge ceramsite cement concrete increased with CO$_2$ curing time. This is ascribed to the fact that the application of CO$_2$ curing on sludge ceramsite is effective in decreasing its pores [25]. Therefore, the water absorption capacity was decreased by the CO$_2$ curing time, eventually leading to an increase in the slump of fresh sludge ceramsite cement concrete.

Figure 5. The slump of fresh sludge ceramsite cement concrete.

3.3. The Mechanical Strengths of Sludge Ceramsite Cement Concrete

The mechanical strengths of sludge ceramsite cement concrete are illustrated in Figure 6. As shown in Figure 6, the flexural and compressive strengths of sludge ceramsite cement concrete increased with the increasing CO$_2$ curing time. When CO$_2$ curing time ranged from 0 h to 48 h, the increasing rate of flexural strength increased from 0% to 31.7%. Meanwhile, the increasing rate of compressive strength varied from 0% to 28.5%. This is attributed to the fact that CO$_2$ curing can improve the compactness of sludge ceramsite, thus increasing the flexural and compressive strengths of sludge ceramsite cement concrete [26]. Additionally, the values of error bars were lower than 0.15, indicating low values of error bars.
Materials 2022, 15, x FOR PEER REVIEW... coefficient of sludge ceramsite cement concrete. The experiments were carried out after the specimens were standard cured for 28 days, or after the specimens experienced 300 NaCl freeze–thaw cycles. As depicted in Figure 7, the mass loss rate was decreased by the increasing curing time and was increased by higher NaCl freeze–thaw cycles. This is ascribed to the fact that the CO2 curing effectively improves the compactness of sludge ceramsite cement concrete [27–29]. Therefore, when the NaCl freeze–thaw cycles were acted upon the specimens, the less mass on the surface of specimens spalled. The values of the error bars were lower than 0.2, indicating high accuracy of experimental results.

![Figure 6](image_url)  
**Figure 6.** The mechanical strengths of sludge ceramsite cement concrete. (a) The compressive strength. (b) The flexural strength.

### 3.4. The Damage of NaCl Freeze–Thaw Cycles

The mass loss rate of sludge ceramsite cement concrete is shown in Figure 7. As depicted in Figure 7, the mass loss rate was decreased by the increasing curing time and was increased by higher NaCl freeze–thaw cycles. This is ascribed to the fact that the CO2 curing effectively improves the compactness of sludge ceramsite cement concrete [27–29]. Therefore, when the NaCl freeze–thaw cycles were acted upon the specimens, the less mass on the surface of specimens spalled. The values of the error bars were lower than 0.2, indicating high accuracy of experimental results.

![Figure 7](image_url)  
**Figure 7.** The mass loss rate of sludge ceramsite cement concrete.

Figure 8 illustrates the chloride ion permeability coefficient of sludge ceramsite cement concrete. The experiments were carried out after the specimens were standard cured for 28 days, or after the specimens experienced 300 NaCl freeze–thaw cycles. As depicted in Figure 8, the chloride ion permeability coefficient of sludge ceramsite cement concrete increased with the increasing number of NaCl freeze–thaw cycles and decreased with CO2 curing time. This is attributed to the fact that the increasing number of NaCl freeze–thaw cycles increase the expansion of internal cracks in concrete, which increases the chloride ion permeability coefficient [30]. Meanwhile, CO2 curing increases the compactness of the material and delays the expansion of cracks. Therefore, the chloride ion permeability
coefficient of sludge ceramsite cement concrete decreased with the increasing CO₂ curing time [31,32].

![Figure 8](image_url)  
*Figure 8. The chloride ion permeability coefficient of sludge ceramsite cement concrete.*

Figure 9 shows the thermal conductivity of sludge ceramsite cement concrete. It can be found in Figure 9 that the thermal conductivity increased with increasing CO₂ curing time. This is due to the fact that CO₂ curing on the sludge ceramsite can improve the compactness [33]. Meanwhile, higher compactness of solid leads to high thermal conductivity [34]. Additionally, 48 h CO₂ curing on the sludge ceramsite increased the thermal conductivity by 18.5%. Therefore, the thermal conductivity varied inapparently with CO₂ curing.

![Figure 9](image_url)  
*Figure 9. The thermal conductivity of sludge ceramsite cement concrete.*

### 3.5. The Corrosion Resistance of Inner Steel Bars

When steel bars corrode, the rust on the surface results in the cracks of inner specimens. The ultrasonic velocity of reinforced sludge ceramsite cement concrete can be used to reflect the following corrosion. Moreover, when steel bars corrode, the rust on the steel bars’ surface prevents the migration of electrons, leading to an increase in electrical resistance. Therefore, the electrical resistance can be applied in the corrosion resistance of steel bars. The ultrasonic velocity and electrical resistivity of specimens cured in a standard environment for 28 days, or after 300 NaCl freeze–thaw cycles, were applied to reflect the corrosion resistance of reinforced sludge ceramsite cement concrete. The NaCl freeze–thaw cycles were carried out following the steps. After standard curing for 24 days, some specimens...
are immersed in the solution containing 3% NaCl for 4 days, and are moved to the rapid freezing and thawing test box with working temperatures of −15 °C–8 °C.

Figure 10 shows the ultrasonic velocity of reinforced sludge ceramsite cement concrete. It can be observed from Figure 10 that the ultrasonic velocity of reinforced sludge ceramsite cement concrete increased with increasing CO2 curing time. This is attributed to the fact that CO2 curing can make ceramsite denser, thus increasing resistance to chloride penetration [35]. Hence, the corrosion resistance of reinforced sludge ceramsite cement concrete is improved by the application of CO2 curing on sludge ceramsite. Meanwhile, the NaCl freeze–thaw cycles led to a decrease in the ultrasonic velocity. This is ascribed to the fact that frost heave stress and chloride ion erosion caused by NaCl freeze–thaw cycles leads to increasing cracks in inner specimens [36]. Consequently, the ultrasonic velocity of reinforced sludge ceramsite cement concrete was decreased by NaCl freeze–thaw cycles.

Figure 10. The ultrasonic velocity of reinforced sludge ceramsite cement concrete.

The electrical resistivity and the following increasing rate of reinforced sludge ceramsite cement concrete is illustrated in Figure 11. It can be observed in Figure 11 that the electrical resistivity of reinforced sludge ceramsite cement concrete increased with increasing CO2 curing time. The increasing rate of electrical resistivity induced by NaCl freeze–thaw cycles was decreased by the application of CO2 curing on sludge ceramsite. This research findings proves that the application of CO2 curing on sludge ceramsite can improve the corrosion resistance of reinforcement [37–42].

Figure 11. The electrical resistivity of reinforced sludge ceramsite cement concrete. (a) The electrical resistivity. (b) The increasing rate of electrical resistivity.

The SEM microstructure photos of ceramsite cured in CO2 for 0 h and 48 h, respectively, are illustrated in Figure 12. As depicted in Figure 12, ceramsite without CO2 curing
possessed more flocculent parts. Meanwhile, when ceramsite was cured in CO\textsubscript{2} for 48 h, more dense parts were found in ceramsite.

4. Conclusions

This paper provides a method (CO\textsubscript{2} curing on sludge ceramsite) to improve the mechanical properties of silt ceramsite. After investigating the influence of CO\textsubscript{2}-cured sludge ceramsite on the properties of cement concrete, the conclusions can be summarized as follows.

The application of CO\textsubscript{2} curing on sludge ceramsite can increase the cylinder compressive strength by 15.1~34.2% and decrease the water absorption rate by 39.6~82.4%. This reflects the fact that CO\textsubscript{2} curing on sludge ceramsite can improve its compactness.

The addition of CO\textsubscript{2}-cured sludge ceramsite can effectively increase the mechanical strength of cement concrete. Cement concrete with CO\textsubscript{2}-cured sludge ceramsite showed higher compressive strength and the flexural strength than that with normal sludge ceramsite. The increasing rates of the compressive strength and the flexural strength were 11.4~21.6% and 18.7~31.5%.

The NaCl freeze–thaw cycles’ resistance to sludge ceramsite cement concrete was improved by CO\textsubscript{2}-cured sludge ceramsite. The thermal conductivity of ceramsite cement concrete was decreased by the addition of CO\textsubscript{2}-cured sludge ceramsite. The corrosion resistance of inner steel bars was increased by the application of CO\textsubscript{2} curing on sludge ceramsite.
