Dark Matter Haloes and Rotation Curves
via Brans-Dicke Theory

Hongsu Kim*

Astronomy Program, SEES, Seoul National University, Seoul, 151-742, KOREA

Abstract

In the present work, the Brans-Dicke (BD) theory of gravity is taken as a possible theory of k-essence. Then starting with the (already known) Brans-Dicke-Schwarzschild solution which can represent the gravitationally bound static configurations of the BD scalar k-essence, issues like whether these configurations can reproduce the observed properties of galactic dark matter haloes have been addressed. It has been realized that indeed the BD scalar k-essence can cluster into dark matter halo-like objects with flattened rotation curves while exhibiting a dark energy-like negative pressure on larger scales.

I. Introduction

Currently, perhaps the most fashionable candidates for the unified model of dark matter and dark energy with non-trivial dynamics are quintessence and k-essence. The main difference between the two models is that the quintessence models involve canonical kinetic terms and the sound speed of \( c_s^2 = 1 \) while the k-essence models employ rather exotic scalar fields with non-canonical (non-linear) kinetic terms which typically lead to the negative pressure. And the most remarkable property of these k-essence models is that the typical k-essence field can overtake the matter energy density and induce cosmic acceleration only at the onset of the matter-dominated era and particularly at about the present epoch. These models are also expected to provide a successful explanation of the phenomena associated with the dark matter. In the present work, we take the Brans-Dicke (BD) theory of gravity as a possible k-essence theory since it involves probably the simplest form of such non-linear kinetic term for the (BD) scalar field. Besides, the BD scalar field (and the BD theory itself) is not of quantum origin. Rather it is classical in nature and hence can be expected to serve as a very relevant candidate to play some role in the late-time evolution of the universe such as the present epoch. Indeed, the BD theory is the most studied and hence the best-known of all the alternative theories of classical gravity to Einstein’s general relativity. This theory can be thought of as a minimal extension of general relativity designed to properly accommodate both Mach’s principle and Dirac’s large number hypothesis. Namely, the theory employs the viewpoint in which the Newton’s constant \( G \) is allowed to vary with space and time and can be written in terms of a scalar (“BD scalar”) field as \( G = 1/\Phi \). As a scalar-tensor theory of gravity, it involves an adjustable but undetermined “BD-parameter” \( \omega \) and as is well-known, the larger the value of \( \omega \), the more dominant the tensor (curvature) degree and the smaller the value of \( \omega \), the larger the effect of the BD scalar. And as long as we select sufficiently large value of \( \omega \), the predictions of the theory agree perfectly with all the observations/experiments to date. For this reason, the BD theory has remained a viable theory of classical gravity. However, no particularly overriding reason thus far has ever emerged to take it seriously over the general relativity. As shall be presented shortly in this work, here we emphasize that it is the existence of dark matter (and dark energy as well, see) that puts the BD theory over the general relativity as a more relevant theory of classical gravity consistent
with observations that have so far been unexplained within the context of general relativity.

II. Haloes of BD scalar k-essence

In general, the Brans-Dicke theory of gravity is described, in the absence of ordinary matter, by the action

$$S = \int d^4x \sqrt{g} \frac{1}{16\pi} \left[ \Phi R - \omega \nabla_\alpha \Phi \nabla^\alpha \Phi \right]$$

(1)

where $\Phi$ is the BD scalar field representing the inverse of Newton’s constant which is allowed to vary with space and time and $\omega$ is the generic dimensionless parameter of the theory. Extremizing this action then with respect to the metric $g_{\mu\nu}$ and the BD scalar field $\Phi$ yields the classical field equations given respectively by

$$G_{\mu\nu} = R_{\mu\nu} - \frac{1}{2} g_{\mu\nu} R = 8\pi T_{\mu\nu}^{BD}, \quad \nabla_\alpha \nabla^\alpha \Phi = 0$$

where

$$T_{\mu\nu}^{BD} = \frac{1}{8\pi} \left[ \frac{\omega}{\Phi^2} (\nabla_\mu \Phi \nabla_\nu \Phi - \frac{1}{2} g_{\mu\nu} \nabla_\alpha \Phi \nabla^\alpha \Phi) + \frac{1}{\Phi} (\nabla_\mu \nabla_\nu \Phi - g_{\mu\nu} \nabla_\alpha \nabla^\alpha \Phi) \right].$$

(2)

Note that here in the present work, we are interested in the role played by the BD scalar field (i.e., a k-essence) as a dark matter particularly in forming galactic dark matter haloes inside of which the well-known rotation curves have been observed. Since the galactic dark matter haloes are roughly static and spherically-symmetric, we first should look for such dark matter halo-like solution of these BD field equations. Interestingly enough, the Brans-Dicke-Schwarzschild (BDS) spacetime solution to these vacuum BD field equations that happens to meet our above-mentioned needs has been found some time ago in rather a theoretical attempt to construct non-trivial black hole spacetime solutions in BD theory. To summarize, the BDS spacetime solution that can be obtained by setting $a = e = 0$ in the Brans-Dicke-Kerr-Newman (BDKN) solution in eq.(11) of Reference takes the form

$$ds^2 = \Delta^{-2/(2\omega+3)} \sin^{-4/(2\omega+3)} \theta \left[ - \left( 1 - \frac{2M}{r} \right) dt^2 + \frac{1}{\Delta} \left( 1 - \frac{2M}{r} \right)^{-1} dr^2 + r^2 \sin^2 \theta d\phi^2 \right] + \Delta^{2/(2\omega+3)} \sin^{4/(2\omega+3)} \theta \left[ \left( 1 - \frac{2M}{r} \right) \frac{1}{\Delta} \left( 1 - \frac{2M}{r} \right)^{-1} dr^2 + r^2 d\theta^2 \right],$$

(3)

$$\Phi (r, \theta) = \Delta^{2/(2\omega+3)} \sin^{4/(2\omega+3)} \theta$$

where $\Delta = r(r-2M)$. A remarkable feature of this BDS solution is the fact that, unlike the Schwarzschild solution in general relativity, the spacetime it describes is static (i.e.,
non-rotating) but not spherically-symmetric. Of great interest in this earlier construction was the realization that non-trivial black hole solutions different from general relativistic solutions could occur in this BD theory for the generic BD-parameter values in the range $-5/2 \leq \omega < -3/2$ \[8\]. In the present study, however, since we are interested in the galactic halo-like configuration, we do not want this BDS solution to become “black” and this amounts to considering the BDS solution having the value of $\omega$-parameter well outside this range. Besides, we are only interested in whether the self-gravitating k-essence, i.e., the BD scalar field can generally cluster into dark matter halo-like objects which would be the gravitationally bound static solution configurations of super-galactic scale (i.e., the large but finite-$r$ behavior). Therefore, the peculiar microscopic geometrical nature of this BDS solution such as the issue of regularity of the potential Killing horizon (i.e., the finiteness of the invariant curvature polynomials there) addressed in \[8\] or that of seemingly failure of asymptotic flatness and internal infinity nature of the symmetry axis discussed in \[9\] are all irrelevant for the present purposes.

Therefore first, it appears that the BD scalar k-essence can indeed cluster into halo-like configurations as it can be represented by the BDS solution. Our natural next mission is then to ask whether these configurations really can reproduce the properties of dark matter haloes, namely if our BD scalar k-essence model for dark matter can reproduce the flattening of the rotation velocity curves inside these halo configurations consistent with the observations. Thus we now attempt to obtain the rotation curves in our BD scalar k-essence halo. Since henceforth we need concrete “numbers”, we now restore both Newton’s constant $G_0$ and the speed of light $c$ in order to come from the geometrical unit ($G_0 = c = 1$) back to the CGS (or MKS) unit. Then the energy-momentum tensor of the BD scalar field given earlier in eq.(2) now takes the form

$$T^{BD}_{\mu\nu} = \frac{c^4}{8\pi G_0} \left[ \frac{\omega}{\Phi^2} (\nabla_\mu \Phi \nabla_\nu \Phi - \frac{1}{2} g_{\mu\nu} \nabla_\alpha \Phi \nabla^\alpha \Phi) + \frac{1}{\Phi} (\nabla_\mu \nabla_\nu \Phi - g_{\mu\nu} \nabla_\alpha \nabla^\alpha \Phi) \right] \quad (4)$$

and in the BDS solution in eq.(3) above, we should replace $M \rightarrow G_0 M/c^2 \equiv \tilde{M}$ where $G_0$ denotes the present value of the Newton’s constant. Apparently, (4) has the dimension of the energy-momentum density in the CGS unit, $(erg/cm^3)$. We now turn to the computation of energy density profile and (anisotropic) pressure components of the k-essence playing the role of the dark matter by treating the BD scalar field as a (dark matter) fluid. The BD scalar field fluid, however, would fail to be a “perfect” fluid as can readily be envisaged
from the fact that the associated BDS solution configuration is not spherically-symmetric. Namely, its pressure cannot be “isotropic”, i.e., \( P_r \neq P_\theta \neq P_\phi \). Such fluid may be called *imperfect* fluid due to the *anisotropic* pressure components and as such its stress tensor can be written as

\[
T^\text{BD} \, \mu \nu = \begin{pmatrix} -c^2 \rho & 0 & 0 & 0 \\ 0 & P_r & T^\nu_\theta & 0 \\ 0 & T^\theta_r & P_\theta & 0 \\ 0 & 0 & 0 & P_\phi \end{pmatrix}.
\]

And it is to be contrasted to its counterpart of the usual perfect fluid with isotropic pressure given by the well-known form, \( T^\mu_\nu = P \delta^\mu_\nu + (c^2 \rho + P) U^\mu U_\nu = \text{diag}(-c^2 \rho, P, P, P) \) where \( U^\alpha = dX^\alpha/d\tau \) (with \( \tau \) being the proper time) denotes the 4-velocity of the fluid element normalized such that \( U^\alpha U_\alpha = -1 \). Note that in addition to the diagonal entries representing the (anisotropic) pressure components \( T^i_i = P_i \) (where no sum over \( i \)), there are off-diagonal entries \( T^\theta_r, T^\rho_r \) representing a *shear stress* which also results from the failure of spherical symmetry. Thus by substituting the BDS solution given in eq.(3) into the BD energy-momentum tensor in eq.(4) and then setting (4) equal to (5), we can eventually read off the energy density and the pressure components of the BD scalar field imperfect fluid to be

\[
\rho = \frac{c^2}{8\pi G_0 (2\omega + 3)^2 r^2 \Delta} \Delta^{-2/(2\omega+3)} \sin^{-4/(2\omega+3)} \theta \left[ 2(\omega + 1) \left\{ (r - \tilde{M})^2 + \Delta \cot^2 \theta \right\} - (2\omega + 3)\tilde{M}(r - \tilde{M}) \right],
\]

\[
P_r = -\frac{c^4}{8\pi G_0 (2\omega + 3)^2 r^2 \Delta} \Delta^{-2/(2\omega+3)} \sin^{-4/(2\omega+3)} \theta \left[ 2(\omega + 2)(r - \tilde{M})^2 + 2(\omega - 1)\Delta \cot^2 \theta - (2\omega + 3) \left\{ \Delta + \tilde{M}(r - \tilde{M}) \right\} \right],
\]

\[
P_\theta = \frac{c^4}{8\pi G_0 (2\omega + 3)^2 r^2 \Delta} \Delta^{-2/(2\omega+3)} \sin^{-4/(2\omega+3)} \theta \left[ 2(\omega - 1) \left\{ \Delta \cot^2 \theta - (r - \tilde{M})^2 \right\} + (2\omega + 3)(r - \tilde{M})(r - 2\tilde{M}) + \left\{ 4\cos^2 \theta - (2\omega + 3) \right\} \frac{\Delta}{\sin^2 \theta} \right],
\]

\[
P_\phi = -\frac{c^4}{8\pi G_0 (2\omega + 3)^2 r^2 \Delta} \Delta^{-2/(2\omega+3)} \sin^{-4/(2\omega+3)} \theta \left[ 2(\omega + 1)(r - \tilde{M})^2 - \Delta \cot^2 \theta - (2\omega + 3)(r - \tilde{M})(r - 2\tilde{M}) \right]
\]

\[
T^r_\theta = \Delta T^\theta_r = \frac{c^4}{8\pi G_0 (2\omega + 3)^2 r^2 \Delta} \cot \theta \Delta^{-2/(2\omega+3)} \sin^{-4/(2\omega+3)} \theta \left[ 4\omega(r - \tilde{M}) - (2\omega + 3)(r - 2\tilde{M}) \right].
\]

Note that the off-diagonal components \( T^r_\theta, T^\theta_r \) are odd functions of \( \theta \) while the diagonal components \( \rho, P_r, P_\theta, P_\phi \) are even functions of the polar angle under \( \theta \rightarrow (\pi - \theta) \).
a result, the off-diagonal components vanish (i.e., no shear stress survives) if we average
over this polar angle to get a net stress. Thus, first the equation of state of this BD scalar
k-essence fluid forming a galactic halo is given by
\[
w = \frac{P}{c^2 \rho} = -\frac{2(\omega + 2)(r - \bar{M})^2 + 2(\omega - 1)\Delta \cot^2 \theta \Delta - (2\omega + 3) \left\{ \Delta + \bar{M}(r - \bar{M}) \right\}}{(2\omega + 1) \left\{ (r - \bar{M})^2 + \Delta \cot^2 \theta \right\} - (2\omega + 3)\bar{M}(r - \bar{M})}
\] (7)
where \( P = P_r \). Namely, \( P = w(r, \theta)c^2\rho \) with \( w(r, \theta) \sim O(1) \) meaning that this k-essence
fluid is essentially a barotropic fluid but with “position-dependent” coefficient \( w(r, \theta) \). Note
that although the BD scalar k-essence is a candidate for dark matter, it is not quite a
dust. In principle, the speed of sound in this BD scalar field fluid can also be evaluated
via \( c_s^2 = \frac{dP}{d\rho} \) but we shall not discuss it in any more detail in this work. We are now
ready to compute the behavior of rotation curves in the outer region (i.e., at large but
finite-\( r \), say, \( r \gg G_0 M/c^2 \) ) of our BD scalar k-essence halo. To be more precise, for a
galaxy of typical (total) mass \( M \sim 10^{11}M_\odot \), the outer region of its dark matter halo, say,
\( r \sim 10(kpc) \simeq 10^{23}(cm) \) is much greater than \( G_0 M/c^2 \simeq 10^{16}(cm) \) by a factor of \( 10^7 \). Thus
to this end, we first approximate the expressions for the energy density and the (radial)
pressure of the k-essence given in eq.(6) for large-\( r \). They are
\[
\rho \simeq \frac{c^2}{8\pi G_0} \frac{8(\omega + 1)}{(2\omega + 3)^2} \frac{1}{r^2 \sin^2 \theta} \Delta^{-2/(2\omega+3)} \sin^{-4/(2\omega+3)} \theta,
\]
\[
P \simeq -\frac{c^4}{2\pi G_0} \frac{1}{(2\omega + 3)^2} \frac{1}{r^2} \left[ 2(\omega - 1) \cot^2 \theta + 1 \right] \Delta^{-2/(2\omega+3)} \sin^{-4/(2\omega+3)} \theta.
\]
Note that in the above approximations and in the discussions below, it was and it shall be
assumed that the metric function \( \Delta = r(r - 2\bar{M}) \simeq r^2 \) for large-\( r \). It is interesting to note
that as a “k-essence” constituting a dark matter halo, the energy density \( \rho \) of the BD scalar
field is almost certainly positive everywhere (i.e., for both small and large-\( r \)). In the mean
time, its (radial) pressure \( P \) particularly at larger scale (i.e., for large-\( r \)) turns out to be
negative although its sign appears unclear at small scale (i.e., for small-\( r \)).
Finally, we are ready to determine the rotation curve inside our BD scalar k-essence halo.
First in the most naive sense, the apparent rotation velocity of an object at radius \( r \) from
the galactic center is given by the Kepler’s third law, \( v^2 = G_0 M(r)/r \). Thus for our
case, using the BD scalar k-essence energy density profile given earlier, we have
\[
M(r) = \int_0^{2\pi} d\phi \int_{\epsilon}^{\pi} d\theta \int_0^r dr \sqrt{g_{rr}g_{\theta\theta}g_{\phi\phi}} \rho(r, \theta) = (2c^2/G_0) \left\{ (\omega + 1)/(2\omega + 1)(2\omega + 3) \right\} f(\omega) r r^{-2/(2\omega+3)}
\]
and hence

\[ v^2(r) = \frac{G_0 M(r)}{r} = c^2 \frac{2(\omega + 1)}{(2\omega + 1)(2\omega + 3)} f(\omega) r^{-\frac{2}{2\omega + 3}} \]  

(9)

where \( f(\omega) \equiv \int_{-\epsilon}^{\pi} \sin^{-\left[1 + 2/(2\omega + 3)\right]} \theta = 2 \int_0^{1-\delta} dx [1 - x^2]^{-\left(2\omega+4\right)/(2\omega+3)} \) with \( \epsilon, \delta << 1 \). (Note here that the integration over the polar angle \( \theta \) starts not from 0 but from \( \epsilon << 1 \) as the symmetry axis \( \theta = 0 \) of the BDS solution in eq.(3) possesses an internal infinity nature, namely, the symmetry axis is infinite proper distance away as discussed carefully in [9].) It has been known for some time that in order for the BD theory to remain a viable theory of classical gravity passing all the observational/experimental tests to date, the BD \( \omega \)-parameter has to have a large value, say, \( |\omega| \geq 500 \) [5]. In our previous study [8], in the mean time, it has been realized that the static solution to the vacuum BD field equations given in eq.(3) above can turn into a black hole spacetime for \(-5/2 \leq \omega < -3/2\). Thus now for \( |\omega| \geq 500 \), the same static solution eq.(3) we are considering represents just a halo-like configuration with regular geometry everywhere (i.e., having no horizon) which is static but not exactly spherically-symmetric (note that the galactic haloes are also believed to be nearly spherically-symmetric but not exactly). Thus if we substitute a large-\( \omega \) value, say, \( \omega \sim 10^6 \) into eq.(9) above, evidently \( M(r) \sim r \) and hence we get

\[ v(r) \simeq 100 (km/s) \times r^{-\left(1/10^6\right)} \]  

(10)

since for \( \omega \sim 10^6 \), \( f(\omega) \simeq O(1) \). Namely for this large-\( \omega \) value, the rotation curve gets flattened out as \( r^{-\left(10^{-6}\right)} \sim constant \) and its magnitude becomes several hundred \((km/s)\). Indeed, this is in impressive agreement with the data for rotation curves observed in spiral/elliptic galaxies with \( M/L \simeq (10-20)M_\odot/L_\odot \) and in low-surface-brightness (LSB)/dwarf galaxies with \( M/L \simeq (200-600)M_\odot/L_\odot \) (where \( M/L \) denotes the so-called “mass-to-light” ratio given in the unit of solar mass-to-luminosity ratio exhibiting the large excess of dark matter over the luminous matter) [10]. Rotation curves are observed usually via the measurements of the Doppler shift of the 21cm emission line from neutral hydrogen (HI) for distant galaxies and of the light emitted by stars for nearby galaxies [11, 12]. It is also interesting to note that this behavior of the rotation curve in our BD theory k-essence dark matter halo model is independent of the mass of the host galaxy as it should be. Namely, this behavior of the rotation curve comes exclusively from the nature of the dark matter, i.e., the BD scalar field k-essence. We also point out that even if we employ more careful
expression for the rotation velocity curve involving the Doppler shift of light emitted by the orbiting objects (assuming that the k-essence halo is almost spherically-symmetric), namely

\[ v^2(r) = \frac{G_0 M(r)}{r} + 4\pi r^2 G_0 P/c^2 \]  

(with \( P \) being the radial pressure given in eq.(8) above), the conclusions above remain the same.

Next, the equation of state in eq.(7) of this BD scalar k-essence becomes, in the outer region of the galactic dark matter halo (i.e., at large-\( r \)),

\[ w \simeq -\frac{2(\omega - 1) \cos^2 \theta + \sin^2 \theta}{2(\omega + 1)} \]  

which is obviously negative due to the negative pressure (and still positive energy density) in this outer region. Moreover, for the large-\( \omega \) value, i.e., \( \omega \sim 10^6 \) for which the rotation curve gets flattened out that we just have realized, this equation of state at large-\( r \) further approaches \( w \simeq -\cos^2 \theta \simeq -O(1) \). (Incidentally, it is interesting to note that in the vicinity of the equatorial plane \( \theta = \pi/2 \), \( w = 0 \), namely, the BD scalar k-essence behaves like nearly a dust.) This observation is particularly interesting as it appears to indicate that the BD scalar k-essence we are considering possesses dark energy-like negative pressure on larger scales. And this observation is indeed consistent with our previous study that on the cosmological scale, the BD scalar field does exhibit the nature of dark energy possessing the negative pressure.

III. Concluding remarks

In the present work, starting with the (already known) BDS solution which can represent the gravitationally bound static configurations of the BD scalar k-essence, issues like whether these configurations can reproduce the observed properties of galactic dark matter haloes have been investigated. It has been realized that indeed the BD scalar k-essence can cluster into dark matter halo-like objects with flattened rotation curves while exhibiting a dark energy-like negative pressure on larger scales. Thus to conclude, from this success of “BD scalar field as a k-essence” to account for the asymptotic flattening of galaxy rotation curves while forming galactic dark matter haloes plus the original spirit of the BD theory in which the BD scalar field is prescribed not to have direct interaction with ordinary matter fields (in order not to interfere with the great success of equivalence principle), we suggest that the Brans-Dicke theory of gravity is a very promising theory of dark matter. And this implies, among others, that dark matter (and dark energy as well, see [7]) might not be
some kind of unknown exotic “matter”, but the effect resulting from the space-time varying nature of the Newton’s constant represented by a (k-essence) scalar field. Even further, this successful account of the phenomena associated with the dark matter of the present universe via the BD gravity theory might be an indication that the truly relevant theory of classical gravity at the present epoch is not general relativity but its simplest extension, the Brans-Dicke theory with its generic parameter value $\omega \sim 10^6$ fixed by the dark matter observation!
