Abstract

We examine the quantum correlations of spin pairs in the ground state of finite XY chains in a transverse field, by evaluating the quantum discord as well as other related entropic measures of quantum correlations. A brief review of the latter, based on generalized entropic forms, is also included. It is shown that parity effects are of crucial importance for describing the behavior of these measures below the critical field. It is also shown that these measures reach full range in the immediate vicinity of the factorizing field, where they become independent of separation and coupling range. Analytical and numerical results for the quantum discord, the geometric discord and other measures in spin chains with nearest neighbor coupling and in fully connected spin arrays are also provided.

Keywords: Quantum Discord; Quantum Correlations; Spin Chains.
I. INTRODUCTION

The last decades have witnessed the great progress experienced by the interdisciplinary field of quantum information science [1–3], which began with the recognition of the potential of quantum systems and quantum correlations for information processing tasks. While it is well known that quantum entanglement is essential for quantum teleportation [4], super-dense coding [5] and also for achieving exponential speed-up in pure state based quantum algorithms [6], the mixed state based quantum algorithm of Knill and Laflamme [7] showed that such speedup could in principle be achieved in this case without a substantial presence of entanglement [8]. This has oriented the attention to alternative definitions and measures of quantum correlations for mixed states, like the quantum discord [9, 10]. While coinciding with the entanglement entropy for pure states, the quantum discord differs essentially from the entanglement of formation in the case of mixed states, being non-zero in most separable mixed states and vanishing just for states which are strictly classically correlated at least with respect to one of the constituents, i.e., diagonal in a standard or conditional product basis [9]. The result of Ref. [11] showing the existence of a finite discord between the control qubit and the remaining qubits in the circuit of Ref. [7], unleashed a great interest on this measure and several investigations on its fundamental properties [12–15], on its evaluation on spin chains and specific states [16–23] as well as on related measures [24–29], have been recently made (see Ref. [30] for a recent review). Distinct quantum capabilities of states with non-zero discord have also been recently investigated [31–34].

Our aim here is to describe the remarkable behavior of the quantum discord and of other related entropic measures of quantum correlations, in the exact ground state of finite XY chains in a transverse field [20]. We first provide in sections 2–5 a brief review of the quantum discord and of the generalized entropic measures of quantum correlations discussed in Refs. [28, 29]. The latter comprise as particular cases the one-way information deficit [31, 35] and the geometric measure of discord of ref. [27], embedding them in a unified formalism based on majorization [36, 37] and general entropic forms [38]. While their basic features are similar to those of the quantum discord, the possibility of using simple entropic forms permits an easier evaluation, allowing for analytical expressions in some cases, as occurs with the geometric discord of general two qubit states [27].

We then use these measures to investigate, in sections 6–8, the quantum correlations of
spin pairs in the exact ground state of finite XY chains in a transverse field. We review the main results of Ref. [20] on the behavior of the quantum discord in these chains and also add new results concerning the behavior of the geometric discord and other related measures in such chains. The exact ground state of a finite XY chain in a transverse field has a definite spin parity and this fact will be seen to deeply affect the discord and the previous measures for fields lower than the critical field $B_c$. We will show that the essential results in this sector can be interpreted in terms of the discord of mixtures of aligned pairs.

Moreover, these chains can exhibit a factorizing field $B_s$ [39–47], where they have a completely separable ground state. For transverse fields, such eigenstate actually breaks the previous parity symmetry and is hence degenerate, coinciding $B_s$ in a finite chain with the last crossing of the two lowest opposite parity levels [43]. A related remarkable effect is that in the immediate vicinity of $B_s$, pairwise entanglement, though weak, reaches full range [42, 43], regardless of the coupling range. Here we will show that the quantum discord as well as the entropic measures of quantum correlations also reach full range at this point, exhibiting universal features such as being independent of separation and coupling range [20]. Moreover, the value reached by them at this point is non-negligible and does not decrease with size, in contrast with the pairwise entanglement, since these measures are not restricted by the monogamy property [48] which affects the latter (limiting the concurrence [49] to order $n^{-1}$ in an $n$ spin chain if all pairs are equally entangled). Consequently, the behavior of these measures with the applied field and separation will deviate significantly from that of the concurrence or entanglement of formation for $|B| < B_s$. Conclusions are finally discussed in section 9.

II. QUANTUM DISCORD

The quantum discord was originally defined [9, 10] as the difference between two distinct quantum versions of the mutual information, or equivalently, the conditional entropy. For a classical bipartite system $A + B$ described by a joint probability distribution $p_{ij} = p(A = i, B = j)$, the conditional entropy is defined as the average lack of information about $A$ when the value of $B$ is known: $S(A|B) = \sum_j p_j^B S(A|B = j)$, where $p_j^B = \sum_i p_{ij}$ is the probability of outcome $j$ in $B$ and $S(A|B = j) = -\sum_i p_{i/j} \log p_{i/j}$ is the Shannon entropy of the conditional distribution $p_{i/j} = p_{ij}/p_j^B$. It is a non-negative quantity, and can also be
expressed in terms of the joint entropy $S(A, B) = - \sum_{i,j} p_{ij} \log p_{ij}$ and the marginal entropy $S(B) = - \sum_j p_j^B \log p_j^B$ as $S(A|B) = S(A, B) - S(B)$. Positivity of $S(A|B)$ then implies $S(A, B) \geq S(B)$ (and hence $S(A, B) \geq S(A)$) for any classical system.

The last expression for $S(A|B)$ allows a direct quantum generalization, namely

$$S(A|B) = S(\rho_{AB}) - S(\rho_B), \quad (1)$$

where $S(\rho) = -\text{Tr} \rho \log_2 \rho$ is now the von Neumann entropy and $\rho_{AB}$ the system density matrix, with $\rho_B = \text{Tr}_A \rho_{AB}$ the reduced state of subsystem $B$. It is well known, however, that Eq. (1) can be negative \[36\], being for instance negative in any entangled pure state: If $\rho_{AB}^2 = \rho_{AB}$, $S(\rho_{AB}) = 0$ and $S(A|B) = -E(A, B)$, where $E(A, B) = S(A) = S(B)$ is the entanglement entropy \[50\]. The positivity of Eq. (1) provides in fact a basic separability criterion for general mixed states \[51\]: $\rho_{AB}$ separable $\Rightarrow S(A|B) \geq 0$, a criterion which can actually be extended to more general entropies \[52–54\]. We recall that $\rho_{AB}$ is separable if it can be written as a convex combination of product states, i.e. $\rho_{AB} = \sum \alpha q_\alpha \rho_\alpha^A \otimes \rho_\alpha^B$, with $q_\alpha \geq 0$, $\sum \alpha q_\alpha = 1$ \[55\].

A second quantum version of the conditional entropy, closer in spirit to the first classical expression, can be defined \[9\] on the basis of a complete local projective measurement $M_B$ on system $B$ (von Neumann measurement), determined by one dimensional orthogonal local projectors $\Pi_j = |j_B\rangle\langle j_B|$. The conditional entropy after such measurement is

$$S_{M_B}(A|B) = \sum_j p_j^B S(\rho_{A/j}) = S(\rho_{AB}) - S(\rho'_B), \quad (2)$$

where $p_j^B = \text{Tr} \rho_{AB} \Pi_j^B$, with $\Pi_j^B = I_A \otimes \Pi_j$, is the probability of outcome $j$, $\rho_{A/j} = \text{Tr}_B (\rho_{AB} \Pi_j^B)/p_j^B$ is the reduced state of $A$ after such outcome and

$$\rho'_{AB} = \sum_j p_j^B \rho_{A/j} \otimes \Pi_j = \sum_j \Pi_j^B \rho_{AB} \Pi_j^B, \quad (3)$$

is the average joint state after such measurement, with $\rho'_B = \text{Tr}_A \rho'_{AB} = \sum_j p_j^B \Pi_j$. Eq. (2) represents the average lack of information about $A$ after the measurement $M_B$ in $B$ is performed and is clearly non-negative, in contrast with Eq. (1). For a classical system, both quantities (1)–(2) are, however, equivalent. We also mention that for general local measurements, defined by a set of positive operators $E_j$ ($\sum_j E_j = I$), the first expression in (2) is to be used for $S_{M_B}(A|B)$ (with $\Pi_j \rightarrow E_j$).
The quantum discord\(^{9,11}\) can then be defined as the minimum difference between Eqs. (2) and (1):

\[
D_B(\rho_{AB}) = \min_{M_B} [S_{M_B}(A|B)] - S(A|B),
\]

where the minimization is over all local measurements \(M_B\). Due to the concavity of the von Neumann conditional entropy\(^{11}\) with respect to \(\rho_{AB}\),\(^{36}\) Eq. (4) is non-negative\(^{9}\), vanishing just for classically correlated states with respect to \(B\), i.e. states which are already of the general form (3) (a particular case of separable state) and which remain then unchanged under a specific unread local measurement. Such states are diagonal in a “conditional” product basis \(\{|i_j\rangle \equiv |i_jA\rangle \otimes |jB\rangle\}\), with \(|i_jA\rangle\) the eigenstates of \(\rho_{Aj}\).

Eq. (4) is then non-zero not only in entangled states but also in separable states not of the form (3), i.e. those which involve convex mixtures of non-commuting product states, for which the entanglement of formation\(^{56}\) vanishes. It is then a measure of all quantum-like correlations between \(A\) and \(B\). The distinction with entanglement arises nonetheless just for mixed states: For pure states \(\rho_{AB}^2 = \rho_{AB}\), \(S(\rho_{AB}) = 0\) and \(S(\rho_{AB}') = S(\rho_B')\) for any von Neumann measurement, reducing the quantum discord exactly to the entanglement entropy:\(D_A = D_B = E(A,B)\).

Eq. (4) can of course be also understood\(^{10}\) as the minimum difference between the quantum mutual information\(^{36}\) \(I(A:B) = S(A) - S(A|B) = S(\rho_A) + S(\rho_B) - S(\rho_{AB})\), which measures all correlations between \(A\) and \(B\) \((I(A:B) \geq 0\), with \(I(A:B) = 0\) if and only if \(\rho_{AB} = \rho_A \otimes \rho_B\) and the “classical” mutual information \(I_{M_B}(A:B) = S(A) - S_{M_B}(A|B)\), which measures the correlations after the local measurement \(M_B\).

III. GENERALIZED ENTRISTIC MEASURES OF QUANTUM CORRELATIONS

Let us now discuss an alternative approach for measuring quantum correlations\(^{28}\), which allows the direct use of more general entropic forms. We consider a complete local projective measurement \(M_B\) (Von Neumann type measurement) on part \(B\) of a bipartite system initially in a state \(\rho_{AB}\), such that the post-measurement state is given by Eq. (3) if the result is unread. A fundamental property satisfied by the state (3) is the majorization relation\(^{1,36,37}\)

\[
\rho_{AB}' \prec \rho_{AB},
\]

(5)
where $\rho' \prec \rho$ means, for normalized mixed states $\rho, \rho'$ of the same dimension $n$,

$$\sum_{j=1}^{i} p'_{j} \leq \sum_{j=1}^{i} p_{j}, \quad i = 1, \ldots, n - 1.$$ 

Here $p'_{j}, p_{j}$ denote, respectively, the eigenvalues of $\rho'$ and $\rho$ sorted in decreasing order ($p_{j} \geq 0$, $\sum_{j} p_{j} = 1$). Eq. (5) implies that $\rho'_{AB}$ is always more mixed than $\rho_{AB}$: If Eq. (5) holds, $\rho'_{AB}$ can be written as a convex combination of unitaries of $\rho_{AB}$: $\rho'_{AB} = \sum_{\alpha} q_{\alpha} U_{\alpha} \rho_{AB} U_{\alpha}^{\dagger}$, with $q_{\alpha} > 0$, $\sum_{\alpha} q_{\alpha} = 1$ and $U_{\alpha}^{\dagger} U_{\alpha} = I$ [36, 37].

Eq. (5) not only implies that $S(\rho'_{AB}) \geq S(\rho_{AB})$ for the von Neumann entropy, but also $S_{f}(\rho'_{AB}) \geq S_{f}(\rho_{AB})$ (6) for any entropy of the form

$$S_{f}(\rho) = \text{Tr} f(\rho),$$

where $f : [0, 1] \to \mathbb{R}$ is a smooth strictly concave function satisfying $f(0) = f(1) = 0$. As in the von Neumann case, recovered for $f(\rho) = -\rho \log \rho$, these entropies also satisfy $S_{f}(\rho) \geq 0$, with $S_{f}(\rho) = 0$ if and only if $\rho$ is a pure state ($\rho^{2} = \rho$), and $S_{f}(\rho)$ maximum for the maximally mixed state $\rho = I_{n}/n$. Hence, Eq. (5) implies a strict disorder increase by measurement which cannot be fully captured by considering just a single choice of entropy ($S(\rho') \geq S(\rho)$ does not imply $\rho' \prec \rho$). More generally, Eq. (5) actually implies $F(\rho') \geq F(\rho)$ for any Schur concave function $F$ of $\rho$ [37]. Nonetheless, entropies of the form (7) are sufficient to characterize Eq. (5), in the sense that if Eq. (6) holds for all such $S_{f}$, then $\rho' \prec \rho$ [54].

We may now consider the generalized information loss due to such measurement [28],

$$I_{f}^{AB} = S_{f}(\rho'_{AB}) - S_{f}(\rho_{AB}),$$

which is always non-negative due to Eqs. (5)–(6), vanishing only if $\rho'_{AB} = \rho_{AB}$ due to the strict concavity of $f$. Eq. (8) is a measure of the information contained in the off-diagonal elements $\langle ij|\rho_{AB}|i'j'\rangle$ ($j \neq j'$) of the original state, lost in the measurement. The minimum of $I_{f}^{MB}$ among all complete local measurements [28],

$$I_{f}^{B}(\rho_{AB}) = \min_{MB} S_{f}(\rho'_{AB}) - S_{f}(\rho_{AB}),$$

provides then a measure of the quantum correlations between $A$ and $B$ present in the original state and destroyed by the local measurement in $B$: $I_{f}^{B} \geq 0$, vanishing, as the quantum
discord $I^B$, only if $\rho_{AB}$ is already of the form (3), i.e., only if it is diagonal in a standard or conditional product basis.

Again, in the case of a pure state $\rho_{AB} = |\Psi_{AB}\rangle\langle\Psi_{AB}|$, it can be shown [28] that Eq. (9) reduces to the generalized entanglement entropy: $I^A_I = I^B_I = E_I(A, B)$ if $\rho_{AB}^2 = \rho_{AB}$, where $E_I(A, B) = S_I(\rho_A) = S_I(\rho_B)$. The minimizing measurement in this case is the local Schmidt basis for $|\Psi_{AB}\rangle$: $M_B = \{|k^B\rangle\langle k^B|\}$ if $|\Psi_{AB}\rangle = \sum_k \sqrt{p_k} |k^A\rangle \otimes |k^B\rangle$ [28].

In the case of the von Neumann entropy ($S_f(\rho) = S(\rho)$), Eq. (9) becomes the one-way information deficit [31, 35], which coincides with the different version of discord given in the last entry of Ref. [9] (and denoted as thermal discord in [30]). It can be rewritten in this case in terms of the relative entropy [36, 57] $S(\rho||\rho^\prime) = -\text{Tr} \rho (\log \rho^\prime - \log \rho)$ (a non-negative quantity) as

$$I^B_I(\rho_{AB}) \equiv \text{Min}_{M_B} S(\rho^\prime_{AB}) - S(\rho_{AB}) = \text{Min}_{M_B} S(\rho_{AB}||\rho^\prime_{AB}),$$

(10)

where we have used the fact that the diagonal elements of $\rho_{AB}$ and $\rho^\prime_{AB}$ in the basis where the latter is diagonal are obviously coincident. We also note that for these measurements, the quantum discord $I^B$ can be expressed as $D^B = \text{Min}_{M_B} [I^B(\rho_{AB}) - I^B(\rho_B)]$, coinciding then with $I^B$ when the minimizing measurements in (10) and (4) are the same and such that $\rho^\prime_B = \rho_B$.

In the case of the linear entropy $S_2(\rho) = 1 - \text{Tr} \rho^2$, obtained for $f(\rho) = \rho(1 - \rho)$ (i.e., using the linear approximation $\log \rho \rightarrow \rho - I$ in $-\rho \log \rho$), Eq. (9) becomes [28]

$$I^B_2(\rho_{AB}) \equiv \text{Min}_{M_B} \text{Tr}(\rho^2_{AB} - \rho^2_{AB'}) = \text{Min}_{M_B} ||\rho^\prime_{AB} - \rho_{AB}||^2,$$

(11)

where $||O||^2 = \text{Tr} O^\dagger O$ is the squared Hilbert Schmidt norm. This quantity becomes then equivalent to the geometric measure of discord introduced in Ref. [27]. The latter is defined as the last expression in Eq. (11) with minimization over all states diagonal in a product basis, but the minimum corresponds to a state of the form (3) [28]. For pure states, $I^B_2$ becomes proportional to the squared concurrence $C^2_{AB}$ [49] as for pure states $C^2_{AB}$ is proportional to the linear entropy of any of the subsystems [58].

Finally, in the case of the Tsallis entropy $S_q(\rho) = (1 - \text{Tr} \rho^q)/(q - 1)$, $q > 0$, which corresponds to $f(\rho) = (\rho - \rho^q)/(q - 1)$, Eq. (9) becomes [29]

$$I^B_q(\rho_{AB}) = \text{Min}_{M_B} S_q(\rho^\prime_{AB}) - S_q(\rho_{AB}) = \text{Min}_{M_B} \text{Tr} (\rho^q_{AB} - \rho^q_{AB'}),$$

(12)
with \( I_q \) reducing to the one way information deficit for \( q \to 1 \) (as \( S_q(\rho) \to S(\rho) \)), and to the geometric discord for \( q = 2 \). This entropy allows then a simple continuous shift between different measures.

When considering qubit systems, we will normalize entropies such that \( S_f(\rho) = 1 \) for a maximally mixed two-qubit state \( \rho \) (i.e., \( 2f(1/2) = 1 \)), implying that all \( I^B_f \) will take the value 1 in a maximally entangled two-qubit state (Bell state). This implies setting \( \log \equiv \log_2 \) in the von Neumann entropy, \( S_2(\rho) = 2(1 - \text{Tr} \, \rho^2) \) in the linear case (such that \( I^B_2 = 2\text{Min}_{M_B} ||\rho'_{AB} - \rho_{AB}||^2 \)) and \( S_q(\rho) = (1 - \text{Tr} \, \rho^q)/(1 - 2^{1-q}) \) in the Tsallis case.

### IV. General Stationary Conditions for the Least Disturbing Measurement

The stationary condition \( \delta I^M_B(\rho_{AB}) = 0 \) for the quantity \( \mathcal{S}_q \), obtained by considering a general variation \( \delta |j_B\rangle = (e^{i\delta h_B} - I)|j_B\rangle \approx i\delta h|j_B\rangle \) of the local measurement basis, where \( h_B \) is an hermitian local operator, reads \[ 29 \]

\[
\text{Tr}_A[f'(|\rho'_{AB}\rangle\rangle,\rho_{AB}] = 0, \tag{13}
\]
i.e., \( \sum_i [f'(p^i_k)|i\rangle\langle j\rangle|\rho_{AB}|i\rangle\langle j\rangle - f'(p^i_k)|i\rangle\langle j\rangle|\rho_{AB}|i\rangle\langle j\rangle] = 0 \), where \( f' \) denotes the derivative of \( f \) and \( \langle i\rangle\langle j\rangle|\rho_{AB}|i\rangle\langle j\rangle = \delta_{i\prime}p^i_j \). In the case of the geometric discord, \( f'(|\rangle\langle\rangle) \propto I - 2\langle\rangle \) and Eq. \( \text{(13)} \) reduces to \( \text{Tr}_A[\rho'_{AB},\rho_{AB}] = 0 \). In the case of the quantum discord \( \mathcal{S} \), Eq. \( \text{(13)} \) should be replaced for these measurements by \[ 29 \]

\[
\text{Tr}_A[f'(|\rho'_{AB}\rangle\rangle,\rho_{AB}] - [f'(|\rho'_{B}\rangle\rangle,\rho_B] = 0, \tag{14}
\]
with \( f(|\rangle\langle\rangle) = -\log \rho \), due to the extra local term.

Eqs. \( \text{(13)} - \text{(14)} \) allow us to identify the stationary measurements, from which the one providing the absolute minimum of \( I^M_B \) (least disturbing measurement) is to be selected. For instance, if there is a standard product basis where \( \langle i|\rho_{AB}|i\rangle' = \delta_{ij}p^i_j \) and \( \langle i|\rho_{AB}|i\prime\rangle' = \delta_{ij}p^i_j \), such that the only off-diagonal elements are \( \langle i|\rho_{AB}|i\prime\rangle' \) with \( i \neq i' \) and \( j \neq j' \), a measurement in the basis \( \{|j_B\rangle\} \) is clearly stationary for all \( I^B_f \), as Eq. \( \text{(13)} \) is trivially satisfied, leading to a universal stationary point \[ 29 \]. It will also be stationary for the quantum discord.

An example of such basis is the Schmidt basis for a pure state, \( |\Psi_{AB}\rangle = \sum_{k=1}^{n_s} \sqrt{p_k} |kk\rangle \), with \( |kk\rangle \equiv |k_A\rangle \otimes |k_B\rangle \) and \( n_s \) the Schmidt rank, since \( \langle kl|\rho_{AB}|k'l'\rangle = \delta_{kl}\delta_{k'l'} \sqrt{p_kp_{k'}} \) for...
\( \rho_{AB} = |\Psi_{AB}\rangle\langle \Psi_{AB}|. \) The same holds for a mixture of a pure state with the maximally mixed state,

\[ \rho_{AB}(x) = x|\Psi_{AB}\rangle\langle \Psi_{AB}| + \frac{1-x}{n}I_n, \]

(15)

where \( n = n_A n_B \) and \( x \in [0, 1] \). The Schmidt basis provides in fact the actual minimum of \( I_f^B(x) \equiv I_f^B(\rho_{AB}(x)) \) \( \forall x \in [0, 1] \), as shown in Ref. \[28\]. This implies the existence in this case of a universal least disturbing measurement, and of a concomitant least mixed post-measurement state, such that \( \rho'_{AB} \) majorizes any other post-measurement state. We can then obtain a closed evaluation of \( I_f^B \) for this case \( \forall S_f \) \[28\], which shows some of its main features:

\[ I_f^B(x) = \sum_{k=1}^{n_s} f\left(\frac{x(np_k - 1)}{n} + 1\right) - f\left(\frac{x(n - 1) + 1}{n}\right) - (n_s - 1)f\left(\frac{1-x}{n}\right). \]

(16)

If \( n_s > 1 \), it can be shown that \( I_f^B(x) > 0 \) for \( x > 0 \), being a strictly increasing function of \( x \) for \( x \in [0, 1] \) if \( f(p) \) is strictly concave. Moreover, a series expansion for small \( x \) leads to \( I_f^B(x) \approx \alpha x^2\left(1 - \sum_{k=1}^{n_s} r_k^2\right) \), where \( \alpha = -f''(1/n)/2 \geq 0 \), indicating a universal quadratic increase with increasing \( x \) if \( f''(1/n) \neq 0 \) \[28\]. This behavior is then similar to that of the quantum discord \[9\] and quite distinct from that of the entanglement of formation, which requires a finite threshold value of \( x \) for acquiring a non-zero value.

V. THE TWO QUBIT CASE

Let us now examine the particular case of a two qubit system. A general two-qubit state can be written as

\[ \rho_{AB} = \frac{1}{4}(I + r_A \cdot \sigma_A + r_B \cdot \sigma_B + \sigma_A^I J \sigma_B), \]

(17)

where \( I \equiv I_2 \otimes I_2 \) denotes the identity, \( \sigma_A = \sigma \otimes I_2 \) and \( \sigma_B = I_2 \otimes \sigma \). Due to the orthogonality of the Pauli matrices, we have \( r_A = \langle \sigma_A \rangle \), \( r_B = \langle \sigma_B \rangle \) and \( J = \langle \sigma_A^I \sigma_B \rangle \), i.e., \( J_{\mu \mu'} = \langle \sigma_{A\mu} \sigma_{B\mu'} \rangle \), where \( \mu, \mu' = x, y, z \) and \( \langle O \rangle = \text{Tr} \rho_{AB} O \).

A general local projective measurement in this system is just a spin measurement along a unit vector \( k \), and is represented by the orthogonal projectors \( \frac{1}{2}(I \pm k \cdot \sigma) \). Therefore, the most general post-measurement state \[13\] reads

\[ \rho'_{AB} = \frac{1}{4}(I + r_A \cdot \sigma_A + (r_B \cdot k)k \cdot \sigma_B + (\sigma_A^I J k)(k \cdot \sigma_B)), \]

(18)
and corresponds in matrix notation (setting \( \mathbf{r} \) and \( \mathbf{k} \) as column vectors) to \( \mathbf{r}_B \to \mathbf{k} \mathbf{k}^t \mathbf{r}_B \) and \( J \to J \mathbf{k} \mathbf{k}^t \). The general stationary condition [13] can be shown to lead to the equation [29]

\[
\alpha_1 \mathbf{r}_B + \alpha_2 J^t \mathbf{r}_A + \alpha_3 J^t J \mathbf{k} = \lambda \mathbf{k},
\]

i.e., \( \mathbf{k} \times (\alpha_1 \mathbf{r}_B + \alpha_2 J^t \mathbf{r}_A + \alpha_3 J^t J \mathbf{k}) = \mathbf{0} \), which determines the possible values of the minimizing measurement direction \( \mathbf{k} \). Here \( (\alpha_1, \alpha_2, \alpha_3) = \frac{1}{2} \sum_{\nu, \nu' = \pm 1} f'(\rho') (\nu, \nu'/\lambda_\nu, \nu'/\lambda_\nu) \), with \( p_\nu' = \frac{1}{4}(1 + \nu \mathbf{r}_B \cdot \mathbf{k} + \nu' \lambda_\nu) \) the eigenvalues of (18) and \( \lambda_\nu = |\mathbf{r}_A + \nu J \mathbf{k}| \). In the case of the quantum discord [3], the additional local term leads to the modified equation [29]

\[
(\alpha_1 - \eta) \mathbf{r}_B + \alpha_2 J^t \mathbf{r}_A + \alpha_3 J^t J \mathbf{k} = \lambda \mathbf{k},
\]

where here \( f(p) = -p \log p \) and \( \eta = \frac{1}{2} \sum_{\nu = \pm 1} \nu f'(\rho_\nu) = \frac{1}{2} \log(p_-/p_+) \), with \( p_\nu = \sum_{\nu'} f''(\rho_\nu') = \frac{1}{2}(1 + \nu \mathbf{r}_B \cdot \mathbf{k}) \) the eigenvalues of \( \rho'_B \). A different approach was provided in Ref. [23].

General analytic solutions of these equations can be obtained in a few cases. For instance, a closed evaluation of \( I_f^B \) for any \( S_f \) is directly feasible for any two-qubit state with maximally mixed marginals, i.e.

\[
\rho_{AB} = \frac{1}{4} (I + \sigma_A J \sigma_B),
\]

for which Eq. (19) reduces to \( J^t J \mathbf{k} = \lambda \mathbf{k} \forall I_f \), indicating that \( \mathbf{k} \) should be an eigenvector of \( J^t J \). Moreover, it can be shown [29] that the minimum corresponds to \( \mathbf{k} \) directed along the eigenvector with the largest eigenvalue of \( J^t J \forall S_f \) (universal least disturbing measurement), such that the post-measurement state [3]–[18] conserves the largest component: By suitable local rotations, \( \sigma_A J \sigma_B \) can be written as \( \sum_{\mu = x, y, z} J_\mu \sigma_{A\mu} \sigma_{B\mu} \), where \( J_\mu \) are the eigenvalues of \( J^t J \) (the same as those of \( J J^t \)), and the least disturbing measurement leads then to \( \rho'_{AB} = \frac{1}{4} (I + \tilde{J}_\mu \sigma_{A\tilde{\mu}} \sigma_{B\tilde{\mu}} \), where \( \tilde{J}_\mu = \text{Max}[J_x, J_y, J_z] \). The final result for \( I_f^B \) (obviously identical to \( I_f^A \) for this state) is [29]

\[
I_f^B (\rho_{AB}) = 2 f\left(\frac{p_1^2 + p_2^2}{2}\right) + 2 f\left(\frac{p_3^2 + p_4^2}{2}\right) - f(p_1) - f(p_2) - f(p_3) - f(p_4),
\]

where \( (p_1, p_2, p_3, p_4) \) are the eigenvalues of \( \rho_{AB} \) sorted in decreasing order \( p_{1,2} = \frac{1 + J_x \pm (J_x - J_y)}{4} \), \( p_{3,4} = \frac{1 - J_x \pm (J_x + J_y)}{4} \) if \( |J_z| \geq |J_x| \geq |J_y| \) and \( J_z \geq 0, J_x \geq 0 \). It is verified that \( I_f^B = 0 \) only if \( p_1 = p_2 \) and \( p_3 = p_4 \), in which case \( \rho_{AB} = \rho'_{AB} \) is a classically correlated state [29].

In the von Neumann case, Eq. (22) is just the quantum discord for this state, as in this case it coincides with the one-way information deficit (\( \rho'_B = \rho_B \) are maximally mixed). In
the case of the linear entropy, Eq. (22) yields the geometric discord and reduces to
\[ I_2^B(\rho_{AB}) = (p_1 - p_2)^2 + (p_3 - p_4)^2. \]

The linear entropy case (11) is obviously the most simple to evaluate, and in this sense the most convenient. A full analytic evaluation for a general two-qubit state was achieved in Ref. [27]. Since \( \text{Tr} \sigma_{\mu} \sigma_{\mu'} = 2 \delta_{\mu \mu'} \), one easily obtains in this case
\[ I_2^B = S_2(\rho'_AB) - S_2(\rho_{AB}) = \frac{1}{2} (\text{tr} M_2 - k^t M_2 k), \quad M_2 = r_B r_B^t + J^t J, \]  
where \( ||J||^2 = \text{tr} J^t J \), \( ||r||^2 = r \cdot r \) and \( M_2 \) is a positive semidefinite symmetric matrix. The minimum of \( I_2^k \) is then obtained when \( k \) is directed along the eigenvector associated with the maximum eigenvalue \( \lambda_1 \) of \( M_2 \), leading to
\[ I_2^B = \text{Min}_k I_2^k = \frac{1}{2} (\text{tr} M_2 - \lambda_1). \]  
It is easily seen that Eq. (19) reduces in this case to the eigenvalue equation \( M_2 k = \lambda k \), such that the stationary directions are those of the eigenvectors of \( M_2 \).

Similarly, the \( q = 3 \) case in the Tsallis entropy, \( S_3(\rho) \propto (1 - \text{Tr} \rho^3) \), can also be fully worked out analytically [29]. We obtain
\[ I_3^B = S_3(\rho'_AB) - S_3(\rho_{AB}) = \frac{1}{4} (\text{tr} M_3 - 2 \text{det} J - k^t M_3 k), \]  
\[ M_3 = r_B r_B^t + J^t J + r_B r_A J + J^t r_A r_B^t, \]  
where \( M_3 \) is again a positive semidefinite symmetric matrix, with \( \text{tr} M_3 = ||r_B||^2 + ||J||^2 + 2 r_A^t J r_B \). Its minimum corresponds then to \( k \) along the eigenvector with the maximum eigenvalue \( \lambda_1 \) of \( M_3 \), which leads to
\[ I_3^B = \text{Min}_k I_3^k = \frac{1}{4} (\text{tr} M_3 - 2 \text{det} J - \lambda_1). \]  
It is again verified that Eq. (19) leads here to the same eigenvalue equation \( M_3 k = \lambda k \), as \( (\alpha_1, \alpha_2, \alpha_3) = (r_B^t + r_A^t J, r_B^t k, 1) \). In the case of the state (21), we obtain [29], \( I_3^B = (p_1 - p_2)^2 (p_1 + p_2) + (p_3 - p_4)^2 (p_3 + p_4) \).

It should be stressed that for the case of two qubits, these two entropies, \( S_2 \) and \( S_3 \), lead to the same entanglement monotone [60], since for an arbitrary single qubit state they become identical: [28, 29] \( S_2(\rho_A) = S_3(\rho_A) = 1 - ||r_A||^2 \) for \( \rho_A = \frac{1}{2} (I_2 + r_A \cdot \sigma) \). Both quantities \( I_2^B \) and \( I_3^B \) reduce then to the standard squared concurrence [49] \( C^2_{AB} \) in the case of a pure two-qubit state.
VI. THE CASE OF A MIXTURE OF TWO ALIGNED STATES

We are now in a position to examine the important case of a mixture of two aligned spin $1/2$ states \[20\], which will allow us to understand the behavior of the quantum discord of spin pairs in finite ferromagnetic $XY$ chains, particularly in the vicinity of the transverse factorizing field \[20, 39–47\]. We consider the bipartite state

$$\rho_{AB}(\theta) = \frac{1}{2}(|\theta\theta\rangle\langle\theta\theta| + |{-\theta\theta\rangle\langle{-\theta}{\theta}|})$$

\[28\]

$$= \frac{1}{4}(I + \cos \theta(\sigma_A + \sigma_B) + \cos^2 \theta \sigma_A \sigma_B + \sin^2 \theta \sigma_A \sigma_B)$$

\[29\]

where $|\theta\rangle = e^{-i\sigma_y/2}|0\rangle$ denotes the state with its spin aligned along $k = (\sin \theta, 0, \cos \theta)$, and \[29\] corresponds to the spin $1/2$ case, where $|\theta\rangle = \cos \frac{\theta}{2}|0\rangle + \sin \frac{\theta}{2}|1\rangle$ and we have used the notation of Eq. \[17\]. It is a particular case of $X$ state \[22\], i.e., states that commute with the $S_z$ parity $P_z = -e^{i\pi(\sigma_A + \sigma_B)}/2$ \[29\].

The state \[28\] arises, for instance, as the reduced state of any pair in the $n$-qubit pure states

$$|\Theta_\pm\rangle = \frac{|\theta\theta\ldots\theta\rangle \pm |{-\theta\ldots{-\theta\rangle}}}{\sqrt{2(1 - \langle{-\theta}\theta\rangle^n)}}$$

\[30\]

if the complementary overlap $\langle{-\theta}\theta\rangle^{n-2} (\langle{-\theta}\theta\rangle = \cos \theta$ for spin $1/2$) can be neglected (i.e., $n$ large and $\theta$ not too small). As will be seen in the next sections, the states \[30\] are the actual exact ground states of such chains in the immediate vicinity of the factorizing field.

The state \[28\] is clearly separable, i.e., a convex combination of product states \[55\], but is classically correlated, i.e., diagonal in a product basis, just for $\theta = 0$ or $\theta = \pi/2$. Accordingly, both the quantum discord and all measures \[9\], including the geometric discord, will be non-zero just for $\theta \in (0, \pi/2)$. As seen in Fig. \[1\], they all exhibit similar qualitative features, although significant differences concerning the minimizing measurement arise. Due the symmetry of the state, it is apparent that $D_A = D_B = D$ and $I_f^A = I_f^B = I_f \forall \theta$.

It is rapidly seen from Eq. \[19\] that for this state (as well as any other $X$ state), spin measurements along $x$, $y$ or $z$ are stationary, for both the quantum discord and all measures $I_f$ \[20\]. In the case of the quantum discord, the minimizing measurement for this state (which is of rank 2, and hence minimized through a standard von Neumann measurement \[30\]) is in fact along $x \forall \theta \in (0, \pi/2)$, in which case the eigenvalues of $\rho_{AB}^\prime$ become $p_{\nu'} = \frac{1}{4}(1 + \nu'\sqrt{\cos^2 \theta + \sin^\nu \theta})$, being twofold degenerate. The final result for the quantum discord
FIG. 1. Quantum correlation measures in the mixture of aligned states (28): The quantum discord $D$, the geometric discord $I_2$ and the “cubic” discord $I_3$, as a function of the angle $\theta$. Normalization is such that all measures take the value 1 in a maximally entangled two-qubit state. Due to the symmetry of the state, $D = D^A = D^B$ and $I_f = I^A_f = I^B_f \forall f$.

can then be expressed as [20]

$$D = \sum_{\nu=\pm 1} [2f\left(1 + \nu\sqrt{1 - \frac{1}{4}\sin^2 2\theta}\right) - f\left(1 + \nu\cos^2 \theta\right) + f\left(1 + \nu\cos \theta\right)] - 1,$$

where $f(p) = -p \log_2 p$. It is maximum at $\theta \approx 1.15\pi/4$. For $\theta \approx 0$, $D$ vanishes quadratically ($D \propto \theta^2$) whereas for $\theta \to \pi/2$, $D \propto (\pi/2 - \theta)^2 (-\log_2(\pi/2 - \theta)^2 + c)$.

On the other hand, the geometric discord (11) and the “cubic” discord ($q = 3$ in Eq. (12)) can be directly evaluated using Eqs. (24)–(27). We obtain [29]

$$I_2 = \begin{cases} \frac{1}{2} \sin^4 \theta & \theta < \theta_{c_2} \\ \frac{1}{2} \sin^2 \theta + \cos^4 \theta & \theta > \theta_{c_2} \end{cases},$$

$$I_3 = \begin{cases} \frac{1}{4} \sin^4 \theta & \theta < \theta_{c_3} \\ \frac{1}{4}(\cos^2 \theta + 3 \cos^4 \theta) & \theta > \theta_{c_3} \end{cases},$$

where $\cos^2 \theta_{c_2} = 1/3$ ($\theta_{c_2} \approx 0.61\pi/2$) and $\cos^2 \theta_{c_3} = (\sqrt{17} - 3)/4$ ($\theta_{c_3} \approx 0.64\pi/2$), the minimizing measurement direction changing abruptly from $z$ to $x$ at $\theta = \theta_c$ as $\theta$ increases, in contrast with the quantum discord. Both $I_2$ and $I_3$ exhibit therefore a cusp like maximum at $\theta = \theta_c$, as seen in Fig. 1. It is also seen from Eqs. (32)–(33) that these quantities vanish as $\theta^4$ for $\theta \to 0$, whereas for $\theta \to \pi/2$ they vanish quadratically ($\propto (\pi/2 - \theta)^2$). For completeness, it should be also mentioned that the behavior of the least disturbing local measurement for this state depends actually on the choice of entropy. For instance, in the von Neumann case
(where Eq. (9) becomes the one-way information deficit (10)), we obtain instead a smoothed $z \to x$ transition for the minimizing measurement direction, which evolves continuously from $z$ to $x$ in a small intermediate interval [29].

VII. XYZ SPIN CHAINS AND TRANSVERSE FACTORIZING FIELD

Let us now use the previous measures and results to analyze the quantum correlations between spin pairs in a chain of spins $s_i$. We will consider finite chains with XYZ couplings of arbitrary range immersed in a transverse magnetic field, not necessarily uniform, such that the Hamiltonian reads

$$H = \sum_i B^i s_{iz} - \frac{1}{2} \sum_{\mu=x,y,z} \sum_{i,j} J^{ij}_\mu s_{i\mu} s_{j\mu},$$

where $s_{i\mu}$ denote the components of the local spin $s_i$ (assumed dimensionless). We first remark that the Hamiltonian (34) always commutes with the total $S_z$ parity or phase flip

$$P_z = \otimes_{i=1}^n \exp[-i\pi(s_{iz} - s_i)],$$

irrespective of the coupling range, anisotropy, geometry or dimension of the array. Hence, non-degenerate eigenstates will have a definite parity. In fact, the ground state of finite chains will typically exhibit a series of parity transitions as the field increases from 0, before ending in an almost aligned state for sufficiently large fields.

A related remarkable effect in these chains is the possibility of exhibiting a completely separable exact eigenstate at a factorizing field. The existence of a factorizing field was first discussed in Ref. [39], and its properties together with the general conditions for its existence were recently analyzed in great detail by several authors [20, 40–47]. At the transverse factorizing field, finite XYZ chains actually exhibit a pair of completely separable and degenerate parity breaking exact eigenstates [43, 45], which can be ground states under quite general conditions. In such a case the transverse factorizing field corresponds to a ground state parity transition (typically the last parity transition [43, 45]), where the lowest energy levels of each parity subspace cross and enable the formation of such eigenstates. Let us notice that while these lowest levels become practically degenerate in a large chain for fields $|B| < B_c$, they are not exactly degenerate in a finite chain, except at crossing points [43, 45, 61, 62].
Let us then first describe the general conditions for which a separable parity breaking state of the form

$$|\Theta\rangle = |\theta_1 \ldots \theta_n\rangle = \bigotimes_{j=1}^{n} \exp[-i\theta_j s_{jy}]|0_j\rangle,$$

(36)

where $s_{jz}|0_j\rangle = -s_j|0_j\rangle$, can be an exact eigenstate of (34). By inserting (36) in the equation $H|\Theta\rangle = E|\Theta\rangle$, it can be shown that such conditions are valid for arbitrary spins $s_i$. They determine, for instance, the values of $J_{ij}^{ij}$ and $B^i$ in terms of $J_{x}^{ij}, J_{z}^{ij}, s_i$ and $\theta_i$. A careful engineering of couplings and fields can then always produce a chain with such eigenstate, for any chosen values of $\theta_i$. It is also apparent that this eigenstate is degenerate, since $P_z|\Theta\rangle = |\Theta\rangle = \bigotimes_{j=1}^{n} \exp[i\theta_j s_{jy}]|0_j\rangle$ will have the same energy (and differ from $|\Theta\rangle$ if $\sin \theta_j \neq 0$ for some $j$), indicating that these fields necessarily correspond to the crossing of two opposite parity levels. Each local state in the product (36) is a local coherent state. We also note that any state $\bigotimes_{j=1}^{n} e^{-i\theta_j s_{jy}}|0_j\rangle$ can be written, except for a normalization factor, in the form (36) by allowing a complex $\theta_j$ [45]. Eqs. (37)–(38) are then generally valid for such type of states.

The second equation (38) cancels the matrix elements of $H$ between $|\Theta\rangle$ and one spin excitations, and is then a “mean field-like” equation, i.e., that which arises when minimizing the average energy $\langle \Theta|H|\Theta\rangle$ with respect to the $\theta_i$, for fixed fields and couplings. The first equation (37) ensures that the minimizing separable state is an exact eigenstate, by cancelling the residual matrix elements of $H$ connecting $|\Theta\rangle$ with the remaining states (two-spin excitations). It can be also shown [45] that in the ferromagnetic-type case

$$|J_{ij}^{ij}| \leq J_{x}^{ij} \quad \forall i, j,$$

(39)

where all off-diagonal elements of $H$ in the standard basis of $s_z$ eigenstates are real and negative, the state (36) is necessarily a ground state if $\theta_j \in (0, \pi/2) \forall j$, as the exact ground state must have (or can be chosen to have if degenerate) expansion coefficients of the same sign in this basis (different signs will not decrease $\langle H\rangle$), and hence cannot be orthogonal to $|\Theta\rangle$ [43, 45].

15
In particular, a uniform solution $\theta_j = \theta \forall j$, leading to $|\Theta\rangle = |\theta \ldots \theta\rangle$, is feasible if the coupling anisotropy
\[
\chi = \frac{J_{ij}^y - J_{ij}^z}{J_{ij}^y - J_{ij}^z}
\]
(40)
is constant $\forall i, j$ and non-negative \[45\]. Of course, if $\chi > 1$ we can change it to $\chi \in (0, 1)$ by swapping $x \leftrightarrow y$ through a rotation of $\pi$ round the $z$ axis. In such a case, Eqs. (37)–(38) lead to
\[
\cos^2 \theta = \chi,
\]
(41)
\[
B^i = \sqrt{\chi} \sum_j (J_{ij}^y - J_{ij}^z)(s_j - \frac{1}{2}\delta_{ij}),
\]
(42)
where Eq. (42) holds for $\sin \theta \neq 0$.

Eqs. (41)-(42) allow, for instance, the existence of a factorizing field for uniform first neighbor couplings $J_{ij}^\mu = J_\mu \delta_{j,i+1}$ in a finite linear spin $s$ chain if $\chi = \frac{J_y - J_z}{J_x - J_z} > 0$, both in the cyclic case ($J_{1n}^\mu = J_\mu$), where the factorizing field is completely uniform,
\[
B^i = B_s = 2s\sqrt{\chi}(J_x - J_z),
\]
(43)
as well as in the open case ($J_{1n}^\mu = 0$), where $B^i = B_s$ at inner sites but $B^1 = B^n = B_s/2$ at the borders \[45\]. A fully and equally connected spin $s$ array with $J_{ij}^\mu = 2J_\mu/(n-1) \forall i \neq j$ (Lipkin model \[63, 64\]) will also exhibit a uniform transverse factorizing field at $B = B_s$ if $\chi > 0$ \[43, 65\]. The ensuing state $|\Theta\rangle$ can be ensured to be a ground state in all these cases if $|J_y| \leq J_x$ (when $\chi \in [0, 1]$). Other possibilities, like solutions with alternating angles \[45\], can also be considered.

**VIII. QUANTUM CORRELATIONS IN THE DEFINITE PARITY GROUND STATES**

Let us now focus on finite spin chains which exhibit a separable parity breaking exact eigenstate $|\Theta\rangle$ at the factorizing field $B_s$. It will be of course degenerate with $|-\Theta\rangle = P_z|\Theta\rangle$. The important point is that the definite parity states
\[
|\Theta_{\pm}\rangle = \frac{|\Theta\rangle \pm |\Theta\rangle}{\sqrt{2(1 \pm \langle -\Theta|\Theta\rangle)}},
\]
(44)
i.e. the states (30) in the uniform case, will also be exact ground states at $B_s$. Moreover, since the exact ground state of a finite chain will actually be non-degenerate away from the
factorizing field (and the other crossing points), it will have a definite parity. Hence, the actual ground state side-limits at $B = B_s$ will be given by the definite parity states (rather than $|\pm \Theta\rangle$). A ground state parity transition $- \rightarrow +$ will then take place as the field increases across $B_s$. While the ground states of each parity sector become degenerate in the large $n$ limit for fields $|B| < B_s$, in finite chains the degeneracy is lifted and the actual ground state will exhibit important correlations arising just from the definite parity effect. For instance, in the immediate vicinity of $B_s$, the pairwise correlations, rather than vanish, will approach the values determined by the states (44). They will then depend on $\theta_i$ and $\theta_j$ for a pair $i, j$, irrespective of the separation $i - j$. In the uniform case, such correlations will then be independent of the separation, since the states (44) will be completely symmetric and will lead to a separation independent pair reduced state $ho_{ij} = \text{Tr}_{ij}|\Theta_\pm\rangle\langle \Theta_\pm|$. In the uniform case, such correlations will then be independent of the separation, since the states (44) will be completely symmetric and will lead to a separation independent pair reduced state $\rho_{ij} = \text{Tr}_{ij}|\Theta_\pm\rangle\langle \Theta_\pm|$ ($ij$ denotes the rest of the chain). Such state is given exactly by the expression

$$\rho_{ij}(\theta) = \frac{|\theta\rangle \langle \theta| + |\theta + \theta\rangle \langle \theta + \theta| + \varepsilon(|\theta\rangle \langle \theta - \theta| + |\theta - \theta\rangle \langle \theta|)}{2(1 + \varepsilon(|\theta\rangle \langle \theta - \theta| + |\theta - \theta\rangle \langle \theta|))}$$

(45)

where $\varepsilon = \pm \cos^{n-2}\theta$ for $s = 1/2$. This parameter is then small for not too small $n$ and $\theta$. In the $\varepsilon \to 0$ limit one recovers the mixture (28).

The concurrence of the state (45) (a measure of its entanglement) depends essentially on $\varepsilon$ and is therefore small, vanishing for $\varepsilon \to 0$ (as in this limit the state (45) becomes separable). It is given explicitly by

$$C = \frac{|\varepsilon| \sin^2 \theta}{1 + \varepsilon \cos^2 \theta}$$

(46)

which is parallel (antiparallel) for $\varepsilon > 0 (\varepsilon < 0)$. Its maximum value is $2/n$ (in agreement with the monogamy property), reached for $\theta \to 0$ in the negative parity case, where the state (30) approaches an $W$-state. In contrast, we have seen that the quantum and geometric discord, as well as the other measures of quantum correlations, do acquire finite and non-negligible values in the mixture (28) (Fig. 1), i.e., in the state (45) even for $\varepsilon \to 0$, entailing simultaneous and coincident finite values for all pairs in the state (30). This implies in turn infinite range of pairwise quantum correlations, as measured by $D$ or $I_f$, at least in the immediate vicinity of the factorizing field $B_s$, where they will be described by the state (28) and will therefore be independent of both separation and coupling range.
FIG. 2. Left: The quantum discord $D$ and the geometric discord $I_2$ between spin pairs in the exact ground state of a fully connected XY spin 1/2 array of $n = 50$ spins with coupling anisotropy $\chi = J_y/J_x = 0.5$, as a function of the scaled transverse applied field $B$. The dotted lines depict the result for the mixture of aligned states (28) at the mean field angle $\cos \theta = B/J_x$, which is almost coincident with the exact result for $|B| < J_x$ and exactly coincident at the factorizing field $B_s = \sqrt{\chi} J_x$. Right: Same quantities for a cyclic chain of $n = 50$ spins with first neighbor XY couplings with the same anisotropy, for a distant pair ($L = 25$). The dotted lines depict again the results for the mixture of aligned states (28) at the mean field angle, which now coincide with the exact results only at the factorizing field $B_s$.

As illustration, we first depict in Fig. 2 the quantum discord and the geometric discord of spin 1/2 pairs for XY couplings ($J^{ij}_z = 0 \forall i, j$) in the ground state of the fully connected array (Lipkin-type model) and of the nearest-neighbor cyclic chain, for anisotropy $J_y/J_x = 0.5$ in the ferromagnetic type case ($J_x > 0$). The emergence of a finite appreciable value of these quantities for $|B| < B_c$, persisting for pairs with large separation even in the case of first neighbor couplings, is then a direct consequence of the definite parity effect. The exact results for $n = 50$ spins were computed by direct diagonalization of $H$ in the Lipkin case (where the ground state belongs to the completely symmetric representation having total spin $S = n/2$), while in the nearest neighbor chain they were obtained through the exact Jordan-Wigner fermionization [60], taking into account the parity effect exactly in the discrete Fourier transform (see for instance Refs. [43, 61, 62]). In both cases the ground state exhibits $n/2$ parity transitions as the field increases from 0, the last one at $B_s$, although for the case depicted ($N = 50$), their effects on $D$ or $I_2$ are not visible in the scale of the figure (they become visible for smaller $n$ [20]).

It is verified that at the factorizing field (43), the exact results for $D$ and $I_2$ in both
FIG. 3. The quantum discord $D$ (left) and the geometric discord $I_2$ (right) between spin pairs with separation $L = 1, 2, \ldots, n/2$ in the exact ground state of a cyclic chain of $n = 50$ spins with first neighbor $XY$ couplings and anisotropy $\chi = 0.5$. The results for all separations are simultaneously depicted. They all merge at the factorizing field $B_s$, where they coincide with the result for the mixture (28) with $\cos \theta = B_s/J_x = \sqrt{\chi}$.

models coincide with those obtained for the mixture (28), i.e., with Eqs. (31) and (32) for $\cos \theta = \sqrt{\chi}$ (Eq. (41)), being then identical and the same for any pair at this point. Moreover, in the fully connected case the exact results for $D$ and $I_2$ are actually practically coincident with those obtained from the mixture (28) (dotted lines) in the whole region $|B| < J_x$ if $\theta$ is the mean field angle satisfying $\cos \theta = B/J_x$ (Eq. (38)), since the ground state is in this region well approximated by the definite parity states (44) or (30), even away from $B_s$. The behavior of $D$ and $I_2$ for $B \in [0, J_x]$ resembles then that obtained for the mixture (28) for $\theta \in [0, \pi/2]$. This is not the case in the chain with first neighbor couplings, where the agreement holds just at $B_s$, and where $D$ and $I_2$ become appreciable only for $|B| < B_c = (J_x + J_y)/2$ (which is smaller than the mean field critical field $J_x$ but slightly above the factorizing field $\sqrt{\chi}$). Nonetheless, the values attained by $D$ and $I_2$ in the whole region $|B| < B_s$ are still quite large, owing to the definite parity effect, although they exhibit the effects of correlations beyond the parity projected mean field description provided by the states (44).

We also depict in Fig. 3 results for $D$ and $I_2$ for all separations $L = 1, \ldots, n/2$ of the spins of the pair, in the nearest neighbor coupling case (in the fully connected model they are obviously identical $\forall L$). It is seen that the values of $D$ and $I_2$ (and the same for $I_3$ or other $I_f$’s) rapidly saturate as $L$ increases in the region $|B| < B_c$, reaching here a finite non-negligible value due to the definite parity effect, whereas for $|B| > B_c$ they are
appreciable just for the first few neighbors \((L = 1, 2)\). In the last region they can be described perturbatively \([20]\).

It is apparent from Figs. 2–3 that the same qualitative information can be obtained either from the quantum discord \(D\) or the geometric discord \(I_2\), except for the type of maximum. That of \(I_2\) is cusp-like due to the sharp \(x \to z\) transition in the minimizing measurement direction that arises as the field increases, which parallels that occurring for the state \(28\) as \(\theta\) decreases (see Fig. 11). Such transition reflects the change in the type of pairwise correlation, and resembles that of the concurrence (which changes from antiparallel to parallel at \(B_s\) [43]). We also mention that while the behavior of \(I_3\) (not shown) is similar to \(I_2\), other \(I_f\) can exhibit a smoothed maximum as the transition from \(x\) to \(z\) in the measurement direction can be continuous \([29]\).

We finally remark that the exact ground state pairwise concurrence in the fully connected case is small (of order \(n^{-1}\) and bounded above by \(2/n\), \([65]\)) such that the entanglement monotones associated with \(D\) and \(I_2\) (the entanglement of formation and the squared concurrence) are very small in the scale of fig. 2. The same occurs with the concurrence of largely separated pairs in the nearest neighbor case \([67]\), which is non-zero (but very small for this anisotropy and size) just in the immediate vicinity of \(B_s\) \([43, 45]\).

IX. CONCLUSIONS

We have examined the behavior of pairwise quantum correlations in the exact ground state of finite ferromagnetic-type XY spin chains in a transverse field, by analyzing the quantum discord as well as other generalized measures of quantum correlations. We have first provided a brief review of the latter, which are based on general entropic forms and defined as the minimum information loss due to a local measurement in one of the constituents. They generalize the one-way information deficit and contain the geometric discord as a particular case, preserving at the same time the basic properties of the quantum discord like reducing to the (generalized) entanglement entropy in the case of pure states and vanishing just for classically correlated states. We have shown that all these measures indicate the presence of long range pairwise quantum correlations for \(|B| < B_c\) in the exact ground state of these chains, which arise essentially from the definite \(S_z\) parity of such state and can be understood in terms of the model based on the mixture of aligned states \([28]\). They all reach full range
at the factorizing field, where they acquire a finite non-negligible constant value which is independent of the pair separation or coupling range and is determined solely by the coupling anisotropy. Such value is exactly described by the states (28) or (45), which also provide a quite reliable description of these correlations for all $|B| < B_c$ for long range couplings, as we have seen in the case of the fully connected model. Parity effects are then seen to be of paramount importance for a proper description of quantum correlations in finite quantum systems. A final comment is that the use of simple entropic forms involving just low powers of the density matrix, like those underlying the geometric discord $I_2$ and the cubic measure $I_3$, enables an easier evaluation, offering at the same time an increased sensitivity of the optimizing measurement to changes in the type of correlation.
