The role of electron-stimulated desorption in focused electron beam induced deposition

Willem F. van Dorp 1, Thomas W. Hansen 2, Jakob B. Wagner 2 and Jeff T. M. De Hosson 1

Abstract

We present the results of our study about the deposition rate of focused electron beam induced processing (FEBIP) as a function of the substrate temperature with the substrate being an electron-transparent amorphous carbon membrane. When W(CO) 6 is used as a precursor it is observed that the growth rate is lower at higher substrate temperatures. From Arrhenius plots we calculated the activation energy for desorption, \( E_{\text{des}} \), of W(CO) 6 . We found an average value for \( E_{\text{des}} \) of 20.3 kJ or 0.21 eV, which is 2.5–3.0 times lower than literature values. This difference between estimates for \( E_{\text{des}} \) from FEBIP experiments compared to literature values is consistent with earlier findings by other authors. The discrepancy is attributed to electron-stimulated desorption, which is known to occur during electron irradiation. The data suggest that, of the W(CO) 6 molecules that are affected by the electron irradiation, the majority desorbs from the surface rather than dissociates to contribute to the deposit. It is important to take this into account during FEBIP experiments, for instance when determining fundamental process parameters such as the activation energy for desorption.

Introduction

When the electron beam in an electron microscope is focused on a sample in the presence of a precursor gas, it can be used to locally modify the sample. This process has gained increasing interest over the past ten years and is named focused electron beam induced processing (FEBIP) [1-3]. The molecules from the precursor gas (transiently) adsorb on the sample surface and dissociate into fragments when they are exposed to the electron beam. If these fragments react with the target material to form a gaseous product, the target is etched locally (focused electron beam induced etching). If on the other hand the fragments form a residue, a deposit grows on the sample surface (focused electron beam induced deposition). In either case, the sample can be modified directly with the electron beam, in principle without the use of any extra processing before or after the electron beam.
Figure 1: (a) An array of dots written at a substrate temperature of 306 K (33 °C) and a dwell time of 3 s per dot. (b) The deposited mass as a function of beam current and substrate temperature. The dwell time was 3 s per dot for all arrays.
beam currents were estimated by correlating the counts of the CCD camera in STEM-mode (in arbitrary units) to the reading of the fluorescent screen in TEM-mode (in A/cm²). The estimated beam currents are given in Table 1 and range between 1 and 6 pA, which is consistent with values reported in literature [20,21]. Figure 1b shows the average deposited mass per dot as a function of beam current and substrate temperature. In this case the dwell time was 3 s per dot for all arrays. From the fact that the deposited mass increases with the beam current, we conclude that the growth is electron-limited at all substrate temperatures.

Table 1: The counts on the CCD camera and the estimated beam current as a function of spot size.

| spot | CCD camera counts (arb. units) | estimated beam current (pA) |
|------|-------------------------------|-----------------------------|
| 10   | 2.1                           | 1.1                         |
| 9    | 3.5                           | 1.9                         |
| 8    | 5.9                           | 3.2                         |
| 7    | 11.0                          | 6.0                         |

The effect of the dwell time is studied by writing arrays of dots with spot 9 at three temperatures, 306 K, 341 K and 371 K. The average deposited mass per dot is plotted as a function of the dwell time in Figure 2a (see below), from which \( E_{\text{des}} \) can be determined. Following the model proposed by Müller et al. [22], the precursor coverage, \( N \) (cm\(^{-2}\)), depends on the adsorption from the gas phase, the diffusion of precursor molecules over the surface, the number of molecules consumed in the reaction with the electrons and desorption to the gas phase:

\[
dN/dt = gF(1 - N/N_0) + D \left( \delta^2 n/\delta r^2 - \delta n/\delta r \right) - \sigma(E)NJ - N/\tau
\]

where \( g \) is the sticking factor, \( F \) is the gas flux, \( N_0 \) is the density of adsorption sites in a monolayer, \( D \) is the diffusion coefficient, \( \sigma(E) \) is the cross section for dissociation, \( J \) is the electron flux, and \( \tau \) is the residence time of the molecules on the surface. The first term describes adsorption of precursor molecules from the gas phase on available sites on the substrate. The second term describes the number of molecules arriving at the writing position due to surface diffusion, the contribution of which depends on the concentration gradient. The last two terms describe dissociation by the electron beam and desorption from the substrate to the gas phase. The growth rate, \( R \) (cm·s\(^{-1}\)), can be defined as:

\[
R = V_{\text{molecule}}\sigma(E)NJ
\]

with \( V_{\text{molecule}} \) (cm\(^3\)) being the volume of a deposited molecule.

Equation 1 has two temperature-dependent terms: diffusion and desorption. If, in a first approach, we assume that the supply of precursor molecules to the writing position through diffusion does not play a significant role, the effect of the substrate temperature follows simply from Equation 1. The residence time \( \tau \) of the precursor molecule on the sample depends on temperature:

\[
\tau = 1/\nu \exp\left( E_{\text{des}}/k_B T \right)
\]

When the substrate temperature increases, the residence time of the molecules on the surface will become shorter and the desorption term in Equation 1 becomes larger. The precursor
coverage, $N$, decreases, which leads to a lower growth rate $R$. In Figure 2a the same data from Figure 1b is plotted again, this time as a function of substrate temperature. The behavior described by Equation 3 is observed in Figure 1b and Figure 2a; for all beam currents the amount of deposited mass becomes smaller at higher temperatures. Based on the data in Figure 2a we made an Arrhenius plot (Figure 2b), with the natural logarithm of the average deposited mass per array as a function of $1/T$. The slope of the fitted linear function is proportional to $E_{\text{des}}/k_B$. The values for $E_{\text{des}}$ we calculated from the data in Figure 2b vary between 17.2 kJ/mol and 23.0 kJ/mol or 0.18 eV and 0.24 eV.

Since the dots are small (a full width at half maximum between 3 and 5 nm), surface diffusion is potentially an important precursor supply mechanism. Both desorption and diffusion are thermally activated according to the same exponential law. For an adsorbed precursor molecule the energy threshold for desorption $E_{\text{des}}$ is much larger than the threshold $E_{\text{diff}}$ to move from one adsorption site to an adjacent one [2]. So while molecules diffuse faster across the surface at higher temperatures, effectively the diffusion path length becomes shorter because desorption will occur sooner. This reduces the total number of precursor molecules that are transported by surface diffusion to the writing location.

We therefore verified whether a contribution of surface diffusion is observed in the measurements. The data presented in Figure 1b (and in Figure 2a) is the result of spot exposures with a fixed dwell time of 3 s. The number of precursor molecules that arrive at the writing location through surface diffusion is time-dependent. If the contribution of the surface diffusion to the precursor transport is significant, this becomes apparent when the dwell time is varied. We deposited arrays with dwell times ranging from 0.1 s to 12.0 s as a function of the substrate temperature, all with spot 9 (i.e., a constant current density). We determine the growth rate $R$ by taking the slope of the fitted linear functions in Figure 3a. In Figure 3b an Arrhenius plot is shown, where $\ln(R)$ is plotted as a function of $1/T$. We found a linear dependency, from which we calculated that $E_{\text{des}} = 21.7$ kJ/mol or 0.22 eV.

The values for $E_{\text{des}}$ obtained from the deposition experiments are collected in Figure 4. It is observed that the value for $E_{\text{des}}$ obtained with varying dwell times (from 0.1 s to 12.0 s) falls within the scatter of the data obtained with a constant dwell time of 3 s. This suggests that surface diffusion does not play a significant role in these experiments. This finding is consistent with the value of the gas pressure. We can calculate the number of precursor molecules striking an area on the surface from the gas phase with [23]:

$$F = 3.513 \times 10^{22} P (MT)^{0.5}$$

with $F$ being the flux of molecules arriving at the surface, $P$ the pressure in Torr, and $M$ the molecular mass. A pressure of 1.7 Pa gives a flux of $1.4 \times 10^{18}$ molecules·cm$^{-2}$·s$^{-1}$, or $1.4 \times 10^4$ molecules·nm$^{-2}$·s$^{-1}$. Assuming a dot diameter of 4 nm and taking into account that both the upper and lower surface of the holey carbon membrane are exposed to the precursor gas, the flux on the dot area is $3.5 \times 10^5$ molecules·s$^{-1}$. In comparison, an estimated 300–1500 molecules W(CO)$_6$ are necessary to form a 4 nm dot [18]. The dwell time per dot is 3 s, which makes the flux of precursor molecules arriving from the gas phase about three orders of magnitude larger than the consumption by the e-beam. Even when the sticking coefficient is smaller than 1, the transport of precursor molecules through the gas phase is sufficient to grow the dots, making the contribution from surface diffusion non-dominant in this experiment.
Figure 4 shows that the activation energy for desorption $E_{\text{des}}$, calculated for W(CO)$_6$, varies significantly, from 17.2 kJ/mol to 23.0 kJ/mol. Assuming a random variation, the average value for $E_{\text{des}}$ is 20.3 kJ/mol (or 0.21 eV).

A reference value for W(CO)$_6$ determined by temperature-programmed desorption (TPD) measurements is 53.8 kJ/mol or 0.56 eV (for desorption from multilayers of W(CO)$_6$) [24]. It is observed that the values found in the FEBIP experiments are lower by a factor of 2.5–3.0. A possible explanation for this difference is the fact that the desorption energy is substrate-dependent. The FEBIP and TPD values have been determined using different substrates (amorphous carbon and Ni(100) [24], respectively). However, this does not explain the large discrepancy between the values. Measurements of $E_{\text{des}}$ for MeCpPt(IV)Me$_3$ (a well-known precursor for FEBIP) differ only by about 10% for the substrates Au(110) and a mixture of amorphous carbon and platinum [25]. This indicates that the factor of 2.5–3.0, which we observed here, cannot be explained solely by a substrate effect.

This conclusion is consistent with the report from Christy for a siloxane [14] and from Li et al. for WF$_6$ [16]. The values for the activation energy Li et al. obtained from FEBIP experiments range from 71 meV to 210 meV, depending on the beam current (51 pA to 3400 pA) and acceleration voltage (5 to 30 kV). Similar to our findings, these values for $E_{\text{des}}$ are a factor of 1.5 to 5.0 lower than the values found by TPD [26-28]. A difference to our results is that the calculated $E_{\text{des}}$ does not decrease strongly with increasing beam current as Li et al. observe. However, this can be explained with a smaller range of beam currents that we use in our experiments. Li et al. varied the beam currents between 51 pA and 3400 pA, in our experiments the estimated beam currents are between 1 and 6 pA.

The results demonstrate that indeed electron-stimulated desorption plays a significant role in FEBIP. The FEBIP value for $E_{\text{des}}$ is three times lower than the TPD value, which we assume is more realistic. In order to find a realistic value for $E_{\text{des}}$ from the FEBIP experiment, the difference between the growth rate at the lowest temperature (306 K) and the highest temperature (371 K) would need to be 25 times larger than it is in the actual experiment. In other words, of the W(CO)$_6$ molecules that are affected by the electron irradiation, the majority desorbs from the surface rather than dissociates to contribute to the deposit.

This effect is not limited to WF$_6$ or W(CO)$_6$, but extends to electron-induced chemistry in general. According to Maday and Yates, “generally many more neutrals than ions are observed in electron-stimulated desorption” [17]. Menzel concludes that “neutrals and ions are observed to desorb under electron impact, with the neutrals contributing more than 95% of the total yield in most cases” [29]. Although the percentage of neutrals may vary with the incident electron energy [29], from our experiments it is clear that it is still significant at energies used in FEBIP. This can be important to take into account when calculating parameters such as residence times, cross sections, etc. from the amount of deposited or etched material in FEBIP experiments.

**Conclusion**

The deposition rate of focused electron beam induced processing (FEBIP) has been studied as a function of the substrate temperature. Using the precursor W(CO)$_6$ it was observed that the growth rate is lower at higher substrate temperatures. The measurements enable us to construct Arrhenius plots based on the measurement data, from which we calculated the activation energy for desorption, $E_{\text{des}}$. We found an average value for $E_{\text{des}}$ of 20.3 kJ or 0.21 eV. This is about 2.5–3.0 times lower than literature values. This difference between values measured with FEBIP and those reported in literature is consistent with findings by Christy [14] and Li et al. [16].

We contribute this discrepancy to electron-stimulated desorption, which is known to occur during electron irradiation. Electron-stimulated desorption is observed for many adsorbates and is induced by secondary electron emission. Our experimental result suggests that, of the W(CO)$_6$ molecules that are affected by the electron irradiation, the majority desorbs from the surface rather than dissociates to contribute to the deposit. This is important to take into account during FEBIP experiments, for instance when determining fundamental process parameters such as the activation energy for desorption.
Experimental

Experiments were performed on a FEI Titan 80-300 environmental scanning transmission electron microscope (STEM). A differential pumping system enabled a pressure of up to 10\(^{-3}\) Pa at the sample, while keeping the rest of the column at high vacuum. The microscope was operated at 300 kV [30]. The STEM images were recorded with the annular dark field (ADF) detector at a camera length of 245 mm (inner detector angle 30 mrad). Before the deposition experiments the microscope and the sample holder were plasma cleaned. The precursor was \(\text{W(CO)}_6\) (CAS 14040-11-0), a low-vapor pressure solid (\(\approx 0.034 \text{ mbar at 25 °C} [31]\)). The precursor pressure during writing was 1.7 Pa. Holey carbon membranes mounted on a Au grid were used as substrates for the FEBIPI. Prior to the deposition experiments the sample was heated to 573 K (300 °C) for 45 min in the microscope at high vacuum conditions (10\(^{-6}\) Pa) in order to minimize contamination during writing.
