ABSTRACT
Finding a list of $k$ teams of experts, referred to as top-$k$ team formation, with the required skills and high collaboration compatibility has been extensively studied. However, existing methods have not considered the specific collaboration relationships among different team members, i.e., structural constraints, which are typically needed in practice. In this study, we first propose a novel graph pattern matching approach for top-$k$ team formation, which incorporates both structural constraints and capacity bounds. Second, we formulate and study the dynamic top-$k$ team formation problem due to the growing need of a dynamic environment. Third, we develop an unified incremental approach, together with an optimization technique, to handle continuous pattern and data updates, separately and simultaneously, which has not been explored before. Finally, using real-life and synthetic data, we conduct an extensive experimental study to show the effectiveness and efficiency of our graph pattern matching approach for (dynamic) top-$k$ team formation.

1. INTRODUCTION

The top-$k$ team formation problem is to find a list of $k$ highly collaborative teams of experts such that every team satisfies the skill requirements of a certain task. Various approaches [1, 2, 15, 22, 23, 34] have been proposed, and fall into two categories in terms of the way to improve the collaborative compatibility of team members: (a) minimizing team communication costs, defined with e.g., the diameter, minimum spanning tree and the sum of pairwise member distances of the induced subgraph [7, 22, 25], and (b) maximizing team communication relations, e.g., the density of the induced subgraph [15, 34]. Further, [10] and [34] consider a practical setting by introducing a lower bound on the number of individuals with a specific skill in a team, and an upper bound of the total team members, respectively.

Example 1: Consider a recommendation network $G_1$ taken from [27] as depicted in Fig. 1 in which (a) a node denotes a person labeled with her expertise, e.g., project manager (PM), software architect (SA), software developer (SD), software tester (ST), user interface designer (UD) and business analyst (BA), and (b) an edge indicates the collaboration relationship between two persons, e.g., (PM1, UD1) indicates PM1 worked well with UD1 within previous projects.

A headhunt helps to set up a team for a software product by searching proper candidates from $G_1$ (ignore dashed edges). A desired team has (i) one PM, and one to two BAs, UD, SAs, SDs and STs, such that (ii) PM should collaborate with SAs, BAs and UD well, and SDs and STs should collaborate with each other well and both with SAs well.

One may verify that existing methods [15, 22, 23, 34], can hardly find a desired team. They only find teams satisfying the skill requirement [15, 22, 23] and the lower bound capacity requirement [10, 34] (condition (i)), and cannot guarantee the specific collaboration relationships among team members, i.e., structural constraints (condition (ii)).

A natural question is how to further capture the structural and capacity constraints in a unified model for team formation? We introduce a revision of graph pattern matching for team formation to fill in this gap. Given a pattern graph $P$ and a data graph $G$, graph pattern matching is to find all subgraphs in $G$ that match $P$, and has been extensively studied in [11, 11, 11, 28, 29, 35]. Essentially, we utilize patterns to capture the structural constraint, and revise the semantics of graph pattern matching for team formation. For instance, a desired team requirement can be specified by the pattern $P_1$ (ignore dashed edges) in Fig. 1 in which nodes represent the skill requirements, edges specify the topology constraint, and the bounds on nodes are the capacity constraint.

Another issue lies in that team formation is accompanied with a highly dynamic environment. It typically needs many efforts to find the ideal teams, and is common for professionals to refine patterns (requirements) multiple rounds [13, 36]. Further, real-life graphs are often big and constantly evolve over time [13]. We show this with an example.

Example 2: Consider $P_1$ and $G_1$ in Example 1 again.

1. One may find that $P_1$ is too restrictive to find any sensible match in $G_1$. Hence, she needs to refine the pattern by updating $P_1$ with $\Delta P_1$, e.g., an edge deletion (SD, ST)$^-$. (2) It is also common that a data update $\Delta G_1$ comes on $G_1$, e.g., an edge insertion (SD, ST)$^+$. (3) Finally, it can be the case when pattern update $\Delta P_1$ and data update $\Delta G_1$ come simultaneously on $P_1$ and $G_1$. 

![Figure 1: Motivation example](image-url)
This motivates us to study the dynamic top-k team formation problem, to handle continuous pattern and data updates, separately and simultaneously. It is known that incremental algorithms avoid re-computing from scratch by re-using previous results \cite{32}. However, incremental algorithms of graph pattern matching for pattern updates has not been investigated, though there exist incremental algorithms of graph pattern matching for dealing with data updates \cite{10,11,14}. Further, it is also challenging for incremental algorithms to handle simultaneous pattern and data updates in a unified way.

**Contributions.** To this end, we introduce a graph pattern matching approach for (dynamic) top-k team formation.

1. We propose team simulation, a revision of traditional graph pattern matching, for top-k team formation (Section 2). It extends existing methods by incorporating the structural and capacity constraints using pattern graphs. To cope with the highly dynamic environment of team formation, we also formulate the dynamic top-k team formation problem (Section 2), for dealing with pattern and data updates, separately and simultaneously.

2. We develop a batch algorithm for computing top-k teams via team simulation (Section 3). We study the satisfiability problem for pattern graphs, a new problem raised in the presence of capacity bounds for graph pattern matching. We also propose two optimization techniques, handling radius varied balls and density based filtering, for speeding up the process of computations.

3. We develop a unified approach to handling the need for both pattern and data updates (Sections 3 and 5). Due to the inherent difficulty of the problem, we propose an incremental strategy based on pattern fragmentation and affected balls by localizing the effects of pattern and data updates, and we develop a unified incremental algorithm for dealing with separate and simultaneous pattern and data updates, with an optimization technique with the early return property for incremental top-k algorithms, an analogy of the traditional early termination property.

4. Using real-life data (CITATION) and synthetic data (SYNTHETIC), we demonstrate the effectiveness and efficiency of our graph pattern matching approach for (dynamic) team formation (Section 5). We find that (a) our method is able to identify more sensible teams than existing team formation methods w.r.t. practical measurements, and (b) our incremental algorithm outperforms our batch algorithm, even when changes reach 36% for pattern updates, 34% for data updates and (25%, 22%) for simultaneous pattern and data updates, and when 29% for continuous pattern updates, 26% for continuous data updates and (20%, 18%) for continuously simultaneous pattern and data updates, respectively.

To our knowledge, this work is among the first to study simultaneous pattern and data incremental computations, no previous work has studied update patterns for incremental pattern matching \cite{10,11,14}, not to mention continuous and simultaneous pattern and data updates. This is the most general dynamic setting for incremental computations.

All detailed proofs are available in the full version \cite{4}.

**Related work.** Previous work can be classified as follows.

Graph simulation \cite{19} and its extensions have been introduced for graph pattern matching \cite{11,12,28,29}, in which strong simulation introduces duality and locality into simulation \cite{29}, and shows a good balance between its computational complexity and its ability to preserve graph topology. Furthermore, \cite{11} already adopts capacity bounds on the edges of pattern graphs via subgraph isomorphism, and \cite{12} uses graph pattern matching to find single experts, instead of a team of experts. In this study, team simulation is proposed for team formation as an extension of graph simulation and strong simulation on undirected graphs with capacity constraints on the nodes of pattern graphs.

There has been a host of work on team formation by minimizing the communication cost of team members, based on the diameter, density, minimum spanning tree, Steiner tree, and sum of pairwise member distances among others \cite{7,9,15,22,25,27,31}, which are essentially a specialized class of keyword search on graphs \cite{0}. Similar to \cite{22}, we are to find top-k teams. However, \cite{22} adopted Lawler’s procedure \cite{26}, and is inappropriate for large graphs. We also adopt density as the communication cost, which shows a better performance \cite{15}, and further require that all team members are close to each other (located in the same balls), along the same line with \cite{7,9,22,24}. Except for simply minimizing the communication cost among team members, \cite{20,22} consider minimizing the cost among team members and team leaders. Different from these work, we introduce structural constraints, in terms of graph pattern matching \cite{11,29}, into team formation, while retaining the capacity bounds on specific team members like \cite{15,31}.

Incremental algorithms (see \cite{10,32} for a survey) have proven usefulness in a variety of applications, and have been studied for graph pattern matching \cite{11,12} and team formation \cite{7} as well. However, \cite{10,11,12,32} only consider data updates, and \cite{7} only considers continuously coming new tasks. In this work, we deal with both pattern and data updates for team formation, and support both insertions and deletions. To our knowledge, this is the first study on pattern updates, and is the most general and practical dynamic setting considered so far.

Query reformulation (a.k.a. query rewriting) is to generate alternative queries that may produce better answers, and has been studied for structured queries \cite{31}, keyword queries \cite{40} and graph queries \cite{30}. However, different from our study of handling pattern updates, the focus of query reformulation is not on incremental computations.

Although top-k queries (see \cite{21} for a survey) have been studied for both graph pattern matching and team formation \cite{22}, they have never been studied for both team formation and graph pattern matching in a dynamic setting.

2. **DYNAMIC TEAM FORMATION**

We first propose team simulation, a revision of traditional graph pattern matching. We then formally introduce the top-k team formation problem via team simulation. We finally present the dynamic top-k team formation problem.

2.1 **Team Simulation**

We first extend pattern graphs of traditional graph pattern matching to carry capacity requirements, and then define team simulation on undirected graphs.

We start with basic notations.

**Data graphs.** A data graph is a labeled undirected graph $G(V, E, l)$, where $V$ and $E$ are the sets of nodes and edges,
respectively; and $l$ is a total labeling function that maps each node in $V$ to a set of labels.

**Pattern graphs.** A pattern graph (or simply pattern) is an undirected graph $P(V_P, E_P, l_P, f_P)$, in which (1) $V_P$ and $E_P$ are the set of nodes and the set of edges, respectively; (2) $l_P$ is a total labeling function that maps each node in $V_P$ to a single label; and (3) $f_P$ is a total capacity function such that for each node $u \in V_P$, $f_P(u)$ is a closed interval $[x, y]$, where $x \leq y$ are non-negative integers.

Intuitively, $f_P(u)$ specifies a range bound for node $u$, indicating the required quantity for the matched nodes in data graphs. Note that for traditional patterns, the capacity bounds carried by patterns.

We now redefine graph simulation on undirected graphs, which is originally defined on directed graphs. Consider pattern graph $P(V_P, E_P)$ and data graph $G(V, E)$.

**Graph simulation.** Data graph $G$ matches pattern graph $P$ via graph simulation, denoted by $P \prec G$, if there exists a binary match relation $M \subseteq V_P \times V$ in $G$ for $P$ such that

1. For each $(u, v) \in M$, the label of $u$ matches one label in the label set of $M$,
2. For each node $u \in V_P$, there exist $v \in V$ such that $(a)$ $(u, v) \in M$, and $(b)$ for each adjacent node $u'$ of $u$ in $P$, there exists an adjacent node $v'$ in $V$ such that $(u', v') \in M$.

For any $G$ that matches $P$, there exists a unique maximum match relation via graph simulation.

We then introduce the notions of balls and match graphs. For a node $v$ in data graph $G$ and a non-negative integer $r$, the ball with center $v$ and radius $r$ is a subgraph of $G$, denoted by $G[v, r]$, such that (1) all nodes $v'$ are in $G[v, r]$, if the number of hops between $v'$ and $v$, $\text{hop}(v', v)$, is no more than $r$, and (2) it has exactly the edges appearing in $G$ over the same node set.

**Match graphs.** The match graph $G_P \text{ w.r.t.} M$. A binary relation $M \subseteq V_P \times V$ is a subgraph $G_M$ of data graph $G$, in which (1) a node $v \in V_S$ if and only if it is in $M$, and (2) it has exactly the edges appearing in $G$ over the same node set.

Intuitively, the match graph $G_M$ is the induced subgraph of $G$ such that its nodes play a role in $M$.

We are now ready to define team simulation, by extending graph simulation to incorporate the locality constraints enforced by balls, and the capacity bounds carried by patterns.

**Team simulation.** Data graph $G$ matches pattern graph $P$ via team simulation $w.r.t.$ a radius $r$, denoted by $P \prec G$, if there exists a ball $G[v, r]$ for each node $v \in V_S$ with $\text{hop}(v, v') \leq r$ and $f_P(u)$.

We refer to $G_M$ as a perfect subgraph of $G_P \text{ w.r.t.} P$.

Intuitively, (1) pattern graphs capture the structural and capacity constraints, and (2) a perfect subgraph $G_M$ of pattern $P$ corresponds to a desired team, which is required to satisfy the following conditions: (a) $G_M$ itself is located in a ball $G[v, r]$ where $t \in [1, r]$ as a match graph; and (b) $G_M$ satisfies the capacity constraints carried over pattern $P$.

**Example 3:** Consider pattern $P$ and data graph $G_1$ in Fig. 1 and team simulation with $r = 2$ is adopted.

One can easily verify that $P$ matches $G_1$ via team simulation, i.e., $P \prec G_1$, as (a) there is a perfect subgraph in in ball $G[PM_1, 2]$, i.e., the connected component of $G_1$ containing $PM_1$, which maps $PM_1$, BA, UD, SA, SD and ST in $P_1$ to $PM_1$, $BA_1$, $\{UD_1, UD_2\}$, $\{SA_1, SA_2\}$, $\{SD_1, SD_2\}$ and $\{ST_1, ST_2\}$ respectively, and, moreover, (b) the capacity bounds on all pattern nodes are satisfied.

**Remarks.** (1) Team simulation differs from graph simulation and strong simulation in the existence of capacity bounds on pattern graphs and its ability to capture matches on undirected graphs.

(2) Different from strong simulation with a fixed radius for balls (i.e., the diameter of a pattern), team simulation adopts a more natural setting that the radius of balls is auto-adjustable, having a user specified upper bound only.

### 2.2 Top-k Team Formation

Given pattern $P$, data graph $G$, and two positive integers $r$ and $k$, the top-k team formation problem, denoted as $\text{kTF}(P, G, k)$, is to find a list $L_k$ of $k$ perfect subgraphs (i.e., teams) with the top-k largest density in $G$ for $P$, via team simulation.

Here the density $\text{den}_G$ of graph $G(V, E)$ is $|E|/|V|$, where $|E|$ and $|V|$ are the number of edges and the number of nodes respectively, as commonly used in data mining applications. Intuitively, the larger $\text{den}_G$ is, the more collaborative a team is. In this way, not only the two objective functions of existing team formation methods are preserved, i.e., the locality retained by balls and the density function in selecting top-k results, but also the relationships among members and the capacity constraint on patterns.

**Example 4:** Consider $P$, $G_1$ in Fig. 1 and $r = 2$. We simply set $k = 1$, as most existing solutions for kTF only compute the best team.

One may want to look for candidate teams with existing methods, satisfying the search requirement in Example 1 (1) by minimizing the team diameter, which returns the team with $\{BA_3, PM_3, UD_2, SA_4\}$, except $UD_1$, $PM_3$, $UD_3$, $SA_4$.

One may already notice that these teams only satisfy the skill requirement, i.e., condition (i) in Example 1, and cannot guarantee the specific collaboration relationships among team members. Indeed, the team found in (1) and (2) is connected by $BA_3$ only, and the team found in (3) has loose collaborations among its members. That is, existing methods are not appropriate for identifying the desired teams.

When team simulation is adopted, it returns the perfect subgraph in Example 3 with its density = 1.4, satisfying both conditions (i) and (ii), much better than those teams found by the above existing methods.

### 2.3 Dynamic Top-k Team Formation

We now introduce dynamic top-k team formation.

**Pattern updates (AP).** There are five types of pattern updates: (1) edge insertions connecting nodes in $P$, (2) edge
Proposition 1: pattern graphs can be done in low polynomial time.

Example 5: (1) For pattern graph via team simulation, due to the presence of capacity changes for data graphs. It is worth mentioning that kTF deletions disconnecting nodes in P, (4) node deletions removing nodes from P, and (5) capacity changes adjusting the node capacities in P, while P remains connected in all cases.

Data updates (δG). There are four types of data updates, defined along the same lines as the first four types of pattern updates. Further, different from pattern updates, there is no need to keep G connected for data updates.

Dynamic top-k team formation. Given pattern graph P, data graph G, positive integers r and k, and list L_k(P, G) of top-k perfect subgraphs for P in G, a set of pattern updates ∆P and a set of data updates ∆G, the dynamic top-k team formation problem, denoted by kDTF(P, G, k, L_k, ∆P, ∆G), is to find a list of k perfect subgraphs with the top-k largest density for P ⊕ ∆P in G ⊕ ∆G, via team simulation.

Here ⊕ denotes applying changes ∆P to P and ∆G to G, and P ⊕ ∆P and G ⊕ ∆G denote the updated pattern and data graphs. It is worth mentioning that kDTF covers a broad range of dynamic situations, i.e., handling continuously separate and simultaneous pattern and data updates.

3. FINDING TOP-K TEAMS

In this section, we develop a batch algorithm for top-k team formation. We first study the pattern satisfiability problem for team simulation, then introduce two optimization techniques, and finally we present our batch algorithm.

3.1 Pattern Satisfiability

Different from graph simulation [10] and its extensions [11, 20], there exist patterns that cannot match any data graph via team simulation, due to the presence of capacity constraints on patterns. We illustrate this with an example.

Example 5: (1) For pattern P_2 in Fig. 2, one can verify that there exist no data graphs G such that P_2 ⊆ G because (a) for any nodes v in G, if v matches with the node labeled with B_2, then it must match with the node labeled with B_1, and, hence, (b) the capacity upper bound on B_1 should not be less than the lower bound on B_2.

(2) However, pattern P_2 in Fig. 2 is satisfiable as P_2 ⊆ G_2, and pattern P_1 in Fig. 1 is also satisfiable as P_1 ⊆ G_1.

We say that a pattern P is satisfiable iff there exists a data graph G such that P matches G via team simulation, i.e., P ⊆ G. The good news is that checking the satisfiability of pattern graphs can be done in low polynomial time.

Proposition 1: The satisfiability of patterns P can be checked in O(|P|^2) time.

Algorithm batch. As shown in Fig. 4 it takes input as P, G, and two integers r and k, and outputs the top-k densest perfect subgraphs in P for G. It firstly checks whether P is satisfiable (line 1). If so, for each ball G[v, r] in G, it computes the maximum core G_C of G[v, r], and checks whether the density based ball filtering condition holds (lines 3-6). If so, it skips the current ball, and moves to the next one; otherwise, it computes the perfect subgraph G_s of P in G[v, r].

3.2 Batch Algorithm

We then introduce two techniques for optimizing the computation of team simulation.

Handling radius varied balls. kTF is to find top-k teams within balls G[v, t], where v ∈ V and t ∈ [1, r]. However, it is very costly to construct all r|V| balls, and to compute perfect subgraphs in all of them. Indeed it is also not necessary, and it only needs to construct and compute the matches for a number of |V| balls, i.e., the set of balls G[v, r] where v ∈ V and radius is r, and then incrementally compute the perfect subgraphs for balls G[v, t] (t ∈ [1, r−1]) from the match graphs for ball G[v, r], as shown below.

Theorem 2: Given P, ball G[v, r] and G[v, t] (t ∈ [1, r−1]) in G, (1) if P ⊆ G[v, t], then P ⊆ G[v, r]; and (2) G_s (resp. G_r) is the match graph w.r.t. the maximum match relation M (resp. M') in G[v, r] (resp. G[v, t]) for P via graph simulation, then M' ⊆ M, and G_r is a subgraph of G_s.

When we have the match graph G_s in G[v, r] for P via graph simulation, to compute the perfect subgraph in G[v, t] (t ∈ [1, r−1]) for P via team simulation, we need to (1) first identify the subgraph G'_s in G_s belonging to G[v, t], which can be easily identified in the process for constructing G[v, t] without extra computation; (2) check whether G'_s is already a match graph for P in G[v, t] via graph simulation; if not, remove the unmatched nodes and edges from G'_s until find the match graph G''_s for P in G[v, t]. This can be achieved by executing an efficient incremental process in [13], and (3) finally check whether capacity bounds are satisfied. If so, G''_s is the perfect subgraph in G[v, r] for P via team simulation.

Density based ball filtering. We further reduce the number of balls to speedup the process by adopting the density based filtering technique. The key idea is to tell whether a ball is possible to produce one of the final top-k matches.

Given a ball G[v, r], we compute the density upper bound den_{G_s}, where G_s is a subgraph of G[v, r]. If the bound is larger than the density of the current k-th result, i.e., there is a possibility for the ball; Otherwise, the ball is simply ignored to avoid redundant computations.

The trick part is how to efficiently compute the upper bound of den_{G_s} for each ball in G. As the best densest subgraph algorithms are in O(|G|^3) time [17], which is costly, we utilize an important result in [59], shown below.

Lemma 3: Let den_{H_C} and den_{H_d} be the density of the maximum core H_C and the densest subgraph H_d of graph H. Then (1) den_{H_C} ≤ 2 * den_{H_d}; and (2) there exists an algorithm that computes den_{H_d} in O(|E_H|) time [20].

Here the maximum core H_C of a graph H is a subgraph of H whose node degree is at least ρ, where ρ is the maximum possible one. By Lemma 3 we use 2*den_{H_d} as the density upper bound for filtering unnecessary balls.

We are now ready to present our batch algorithm for kTF.

Algorithm batch. As shown in Fig. 4 it takes input as P, G, and two integers r and k, and outputs the top-k densest perfect subgraphs in P for G. It firstly checks whether P is satisfiable (line 1). If so, for each ball G[v, r] in G, it computes the maximum core G_C of G[v, r], and checks whether the density based ball filtering condition holds (lines 3-6). If so, it skips the current ball, and moves to the next one; otherwise, it computes the perfect subgraph G_s of P in G[v, r]
Input: $G(V, E), P(V_P, E_P)$, and positive integers $r$ and $k$. 
Output: Top-$k$ densest teams.

1. If $P$ is unsatisfiable then return nil;
2. $L_k := \emptyset$;
3. for each ball $G[v, r]$ in $G$ do
   4. compute the maximum core $G_C$ of the ball $G[v, r]$;
   5. if $2^{|V|} |G_C| \leq $ the density of the $k$-th result in $L_k$ then
      6. continue;
    7. $G_s := \text{undirSim}(P, G[v, r])$;
    8. if $G_s$ satisfies capacity bounds on $P$ then Insert $G_s$ into $L_k$;
    9. for each ball $G'[v, \ell]$ with $\ell \in [1, r - 1]$ do
       10. $G'_s := \text{incSim}(G_s, P, G[v, \ell])$;
       11. if $G'_s$ satisfies capacity bounds on $P$ then Insert $G'_s$ into $L_k$;
12. return $L_k[0 : k - 1]$.

Figure 3: Algorithm batch

via team simulation by invoking \texttt{undirSim} (line 7, see full version [2]), an adaption from graph simulation [11][19] and checking capacity bounds (line 8). It then computes perfect subgraphs $G'_s$ of $P$ in inner balls $G[v, \ell]$ by invoking \texttt{incSim}, an extension of the data incremental algorithms in [13] and checking capacity bounds (lines 9-11).

**Correctness & complexity analyses.** The correctness of batch is assured by the following.

1. The correctness of \texttt{undirSim} (resp. \texttt{incSim}) can be verified along the same lines as graph simulation [19] (resp. incremental simulation [13]).
2. Theorem 2 and Lemma 3. It takes $O(|P|^2)$ to check pattern satisfiability, $O(|V||P||G|)$ to compute team simulation, $O(r|V||V_P||E|)$ to incrementally compute matches in inner balls, and $O(|V||E|)$ to compute the density of the maximum core for $V$ balls. Thus batch is in $O(|P|^2 + |V||P||G| + r|V||V_P||E|)$. However, actual time is much less due to density based ball filtering and that $O(r|V||V_P||E|)$ is the worst case complexity for incremental process, while $r$ is small, i.e., 2 or 3.

4. A UNIFIED INCREMENTAL SOLUTION

In this section, we first analyze the challenges and design principles of dynamic top-$k$ team formation, and then develop a unified incremental framework for kDTF. For convenience, the notations used are summarized in Table 1.

4.1 Analyses of Dynamic Team Formation

By Theorem 2 pattern $P$ matches a ball $G[v, \ell]$ ($\ell \in [1, r - 1]$), only if $P$ matches ball $G[v, r]$ via graph simulation, and the match results for $G[v, \ell]$ can be derived from the matches for $G[v, r]$. Therefore, the key of the incremental computation is to deal with the balls $G[v, \ell]$ with radius $r$. In the sequel, a ball has a radius $r$ by default.

We first analyze the inherent computational complexity of the dynamic top-$k$ team formation.

**Incremental complexity analysis.** As observed in [22][53], the complexity of incremental algorithms should be measured by the size $|\text{AFF}|$ of the changes in the input and output, rather than the entire input, to measure the amount of work essentially to be performed for the problem.

An incremental problem is said to be bounded if it can be solved by an algorithm whose complexity is a function of $|\text{AFF}|$ alone, and is unbounded, otherwise. Unsurprisingly, the dynamic top-$k$ team formation problem is unbounded, similar to the other extensions of graph simulation [11][15].

**Proposition 4:** The kDTF problem is unbounded, even for $k = 1$ and unit pattern or data updates.

We then illustrate the impact of pattern and data updates on the matching results with an example.

**Example 6:** Continue Example 2 with $\Delta G_1$ and $\Delta P_1$. (1) For $\Delta P_1$, $G[PM_2, 2]$ already matches $P$, and may produce more matched nodes for $P_1 \oplus \Delta P_1$, thus a re-computation for perfect subgraphs is needed. For all other balls, $\Delta P_1$ may turn unmatched nodes to matched and may produce perfect subgraphs, thus re-computation is also needed. (2) For $\Delta G_1$, it produces a new perfect subgraph for $P$ in $G_1 \oplus \Delta G_1$, i.e., the connected component having $PM_2$. We finally discuss the challenges and principles of designing incremental algorithms for kDTF from three aspects.

1. **Impacts of pattern and data updates.** Beyond Proposition 4 and Example 6 one can also verify that (a) unit pattern updates are likely to result in the entire change in previous results, such that all balls need to be accessed and all matches need to be re-computed, and (b) the impact of data updates can also be global, such that the entire data graph may need to be accessed to re-compute matches. Hence, the key is to identify and localize the impacts of pattern and data updates.

2. **Maintenance of auxiliary information.** Auxiliary data on intermediate or final results for $P$ in $G$ are typically maintained for incremental computation [13][53]. How to design light-weight and effective auxiliary structures is critical. One may want to store $M(P, G)$, the match relations of $P$ for all balls in $G$, as adopted by existing incremental pattern matching algorithms for data updates [13]. However, the impact of $\Delta P$ is global, as shown in Example 5. By storing $M(P, G)$, for pattern edge/node deletions, it has to recompute matches for all balls, i.e., the entire $M(P, G)$, thus storing $M(P, G)$ could be useless, not to mention $L_k(P, G)$, the list of top-$k$ perfect subgraphs for $P$ w.r.t. $M(P, G)$.

3. **Support of continuous pattern and data updates.** A practical solution should support continuous pattern and data updates, separately and simultaneously, which further increases difficulties on the design of auxiliary data structures and incremental algorithms.

4.2 A Unified Incremental Framework

Nevertheless, we develop an incremental approach to handling pattern and data updates in a unified framework, by utilizing pattern fragmentation and affected balls to localize
the impacts of pattern and data updates, and to reduce the cost of maintaining auxiliary structures and computations.

(I) Localization with pattern fragmentation. We say that \( \{ P_{f1}(V_{f1}, E_{f1}), \ldots, P_{f_h}(V_{f_h}, E_{f_h}), C \} \) is an \( h \)-fragmentation of pattern \( P(V_P, E_P) \), denoted as \( \mathcal{P}_h \), if (1) \( \bigcup_{i=1}^h V_{f_i} = V_P \), (2) \( V_{f_i} \cap V_{f_j} = \emptyset \) for any \( i \neq j \in [1, h] \), (3) \( E_{f_i} \) is exactly the edges in \( P \) on \( V_{f_i} \), and (4) \( C = E_P \setminus (E_{f1} \cup \ldots \cup E_{f_h}) \).

We also say \( P_{f_i} (i \in [1, h]) \) as a fragment of \( P \), and \( C \) as a cut of \( P \), respectively.

Observe that by pattern fragmentation, a pattern update on \( P \) is either on a fragment \( P_{f_i} \) or on the cut \( C \) of \( P \), and, in this way, the impact of pattern updates is localized. Moreover, graph simulation holds a nice property on pattern fragmentation, as shown below.

**Theorem 5:** Let \( \{ P_{f1}, \ldots, P_{f_h} \} \) be an \( h \)-fragmentation of pattern \( P \). For any ball \( G \) in \( G \), let \( M_i (i \in [1, h]) \) be the maximum match relation in \( G \) for \( P_{f_i} \), via graph simulation, and \( M \) be the maximum match relation in \( G \) for \( P \) via graph simulation, respectively, then \( M \subseteq \bigcup_{i=1}^h M_i \).

We also say that \( M_i \) is a partial match relation in ball \( G \) for \( P \) via graph simulation. By the nature of graph simulation, we can further produce the result for \( P \) in \( \hat{G} \) via team simulation, by a capacity check.

That is, based on pattern fragmentation, we maintain an auxiliary structure for storing fragment-ball matches for incremental computations, i.e., \( M(P, G) w.r.t. \mathcal{P}_h \) that is the maximum match relations for all pattern fragments of \( P \) in all balls of \( G \), via graph simulation. Moreover, its space cost is light-weight, as will be shown in the experimental study.

By storing \( M(P, G) \), we have \( \bigcup_{i=1}^h M_i \) for each \( M_i \), and we can simply update \( M_i \) while leaving other parts untouched. That is, we indeed compute for \( P_{f_i} \oplus \Delta P(G) \), instead of \( P \oplus \Delta P(G) \), and combine all \( P_{f_i} \oplus \Delta P(G) \) to derive \( P \oplus \Delta P(G) \). Even better, the updates \( \Delta P \) on the cut \( C \) of \( P \) only involve with a simple combination process, avoiding the computation for any pattern fragments.

For a better incremental process, we typically want (1) to avoid skewed updates by balancing the sizes of all fragments, and (2) to minimize the efforts to assemble the partial matches of all fragments. Thus we define and investigate the pattern fragmentation problem.

Given pattern \( P \) and a positive integer \( h \), it is to find an \( h \)-fragmentation of \( P \) such that both \( \max(|P_{f_i}| (i \in [1, h])) \) and \( |C| \) are minimized. Intuitively, the bi-criteria optimization problem partitions a pattern into \( h \) components of roughly equal size while minimizing the cut size.

The problem is intractable, as shown below.

**Proposition 6:** The pattern fragmentation problem is \( \text{NP} \)-complete, even for \( h \geq 2 \).

However, \( P \) and \( h \) are typically small in practice \cite{11}, e.g., \( |P| = 15 \) and \( h = 3 \). In light of this, we give a heuristic algorithm, denoted by \text{PFragment}, for the problem, and is shown in the full version \cite{1}. \text{PFragment} works by connecting pattern fragmentation to the widely studied \((k, \nu)\)-BALANCED PARTITION problem \cite{5}, which is not approximable in general, but has efficient and sophisticated heuristic algorithms \cite{23}.

(II) Localization with affected balls (AffBs). We further localize the impact of pattern and data updates with affected balls to avoid unnecessary computations.

We say that a ball in \( G \) is affected \( w.r.t. \) an incremental algorithm \( \mathcal{A} \), and pattern and data updates, if \( \mathcal{A} \) accesses the ball again. We use \(|\text{AffBs}|\) and \(|\text{AffBs}|\) to denote the cardinality and total size of AffBs, respectively.

Indeed, AffBs are those balls with a possibility to have final results \( w.r.t. \) \( \Delta P \) and \( \Delta G \). We only access AffBs, and ignore the rest balls. Specifically, (1) for \( \Delta P \), it allows us to avoid computing updated partial relations for an updated fragment in every ball; and (2) for \( \Delta G \), the locality property of team simulation supports to localize the update impacts to a set of balls whose structures are changed by \( \Delta G \).

(III) Algorithm framework. We now provide a unified incremental algorithm to handle both pattern and data updates, based on pattern fragmentation and affected balls.

Given pattern \( P \) with its \( h \)-fragmentation \( \mathcal{P}_h \), data graph \( G \), two integers \( r \) and \( k \), and auxiliary structures (to be introduced in Section \ref{sec:auxstr}) such as the partial match relations for all pattern fragments and all balls (radius \( r \)), algorithm \text{dynamic} consists of three steps for \( \Delta P \) and \( \Delta G \), as follows.

(1) **Identifying AffBs.** Algorithm \text{dynamic} invokes two different procedures to identify AffBs for separate \( \Delta P \) or \( \Delta G \), respectively. For simultaneous \( \Delta P \) and \( \Delta G \), \text{dynamic} takes the union of the AffBs produced by the two procedures.

(2) **Update partial match relations in AffBs.** For a ball affected by \( \Delta P \), \text{dynamic} updates the partial match relations for the updated pattern fragments with incremental computation; For a ball affected by \( \Delta G \), \text{dynamic} updates the partial match relations for all pattern fragments; And, for a ball affected by both \( \Delta P \) and \( \Delta G \), \text{dynamic} follows the same way as it does for \( \Delta G \) only. Meanwhile, auxiliary structure \text{FBM} (to be seen shortly) is updated for handling continuously separate and simultaneous pattern and data updates.

(3) **Combining partial match relations.** \text{dynamic} combines all partial relations for all AffBs and computes the top-\( k \) perfect subgraphs within them and their inner balls.

Observe that \text{dynamic} handles pattern and data updates, separately and simultaneously, in a unified way.

5. INCREMENTAL ALGORITHMS

In this section, we introduce the details of our incremental algorithm \text{dynamic}, including (a) auxiliary data structures, (b) algorithms \text{dynamicP} and \text{dynamicG} to handle pattern and data updates, respectively, and (c) \text{dynamic} by integrating \text{dynamicP} and \text{dynamicG} together.

5.1 Auxiliary Data Structures

Auxiliary structures fall into two classes: maintain partial matches and handle pattern incremental computing. Consider an \( h \)-fragmentation \( \mathcal{P}_h = \{ P_{f1}, \ldots, P_{f_h}, C \} \) of pattern \( P(V_P, E_P) \), data graph \( G(V, E) \), and pattern updates \( \Delta P \).

(I) **Data structures in the first class** are as follows.

(1) **Fragment status (FS)** consists of \( 2^h \) boolean vectors \( \{ b_1, \ldots, b_h \} \), referred to as type code \( (tc) \), where \( b_i (i \in [1, h]) \) is either 0 or 1. Recall that \( h \) is very small, e.g., 3.

We use \text{FS} to classify the match status of balls in \( G \) into \( 2^h \) types \( w.r.t. \mathcal{P}_h \). For a ball with type code \( \{ b_1, \ldots, b_h \} \), \( b_i \) is 1 iff \( P_{f_i} \) matches the ball via graph simulation.
(2) Ball status (BS) consists of \(|V|\) triples \((bid, cflag, den)\), such that \(bid\) is the id of a ball, \(cflag\) is the id of the latest processed unit pattern update for the ball (initially set to 0), and \(den\) is the density upper bound of subgraphs in the ball.

We use BS to store the basic information for balls in G.

(3) Fragment-ball matches of \(P\) in G, denote as \(M(P, G)\), are \(j \in [1, |h|] \in \bigcup_{i \in [1, |v|]} M(P_{fi}, G[v, r])\), such that \(M(P_{fi}, G[v, r])\) is the maximum match relation for \(P_{fi}\) in ball \(G[v, r]\), via graph simulation, and there are in total \(|V|\) balls.

Here \(M(P, G)\) is used to store match relations for the pattern fragments of \(P\) in all balls of \(G\). Instead of storing a single \(M(P, G)\), we organize \(M(P, G)\) in terms of the match status between pattern fragments and balls, i.e., FS and BS.

(4) Fragment-ball-match index (FBM) links FS and BS together, to form the fragment-ball-match index. Then FBM is linked to \(M(P, G)\). The details are shown below.

For each record of ball \(G[v, r]\) in BS, (a) there is a link from its type code in FS pointing to the record; and (b) there is another link from the record to a set of \(M(P_{fi}, G[v, r])\) \((i \in [1, |h|])\) in \(M(P, G)\), if the type code with which the ball is associated has \(b_i = 1\), i.e., \(M(P_{fi}, G[v, r])\) is not empty.

Intuitively, FBM indexes the partial match relations \(M(P, G)\) based on the match status of balls w.r.t. \(P_h\).

**Example 7:** Consider \(P_1\) and \(G_1\) (both without dashed edges) in Fig. 4(a) \(r = 2, k = 2, h = 2\), auxiliary structures \(M(P, G)\) and FBM that are shown in Fig. 4(a).

(1) Pattern \(P_1\) is divided into fragments \(P_{f1}\) and \(P_{f2}\) by algorithm FPAg, so there are \(2^3 = 4\) type codes in FS.

(2) For balls linked with \(tc\ (1, 1)\), e.g., ball \(G(P_{PM, 2})\), there are matches to both \(P_{f1}\) and \(P_{f2}\) in the ball. Besides, there exist balls \(G(P_{PM, 2})\), \(G(BA, 2)\) and \(G(P_{PM, 2})\) linked with \(tc\ (1, 0)\), \((0, 1)\) and \((0, 0)\) respectively. For simplicity, we use these 4 balls only in the following analysis.

These structures enforce a nice property as follows.

**Theorem 7:** With \(M(P, G)\) and FBM w.r.t. an h-fragmentation of \(P, \Delta P\) and \(\Delta G\), the incremental algorithm dynamic processes \(\Delta P\) and \(\Delta G\) in time determined by \(P, M(P, G)\) and AffBs, not directly depending on \(G\).

We shall prove Theorem 7 by providing specific techniques for dynamic and analyzing its time complexity.

(II) Data structures in the second class are as follows.

(1) **Ball filter (BF)** consists of \(2^h\) boolean vectors \((b_1, \ldots, b_h)\), referred to as filtering code \((fc)\), such that each \(fc\) in BF corresponds to a type code \(tc\) in FS. Each \(b_i\) \((i \in [1, h])\) in an \(fc\) of BF is initially set to 1, and is updated for each unit pattern update \(\delta\) in \(\Delta P\): (a) when \(\delta\) is an edge deletion or a node deletion to \(P_{fi}\), the \(i\)-th bit of all the \(2^h\) filtering codes in BF is set to 0; Otherwise, (b) BF remains intact.

(2) **Update planner (UP)** consists of \(h + 1\) stacks \(T(P_{f1}), \ldots, T(P_{fj}), T(C)\). Stack \(T(P_{fi})\) \((i \in [1, h])\) (resp. \(T(C)\)) records all unit updates in all arrived pattern updates \(\Delta P_1, \ldots, \Delta P_h\) that are applied to fragment \(P_{fi}\) (resp. \(C\)) of \(P\). Initially, all of them are empty, and are dynamically updated for each unit update in each coming set of pattern updates.

5.2 Dealing with Pattern Updates

We present algorithm dynamicP to handle pattern updates \(\Delta P\), following the steps in Section 4.3 and an early return optimization technique for dynamicP.

**Identifying affected balls.** We first develop procedure IdABall to identify AffBs with structures FBM and BF.

**Procedure IdABall.** Given an h-fragmentation \(P_h\) of \(P\), \(\Delta P\), (1) it updates BF by processing all unit updates in \(\Delta P\). (2) For each \(j \in [1, 2^h]\), it then executes a bitwise AND operation \(\&\) between type code \(tc\) of FS in FBM and updated filtering code \(fc_{j, \Delta}\) in BF, i.e., \(tc \& fc_{j, \Delta}\). (3) Finally, if \(tc_{j, \Delta} \& fc_{j, \Delta} = fc_{j, \Delta}\), IdABall refers to BS in FBM to mark the balls with type code \(tc\) as AffBs, and resets \(fc_{j, \Delta}\) to \((1, \ldots, 1)\). The condition \(tc_{j, \Delta} \& fc_{j, \Delta} = fc_{j, \Delta}\) holds as long as (a) the \(i\)-th bit of \(fc_{j, \Delta}\) is 0, i.e., there exists an edge/node deletion on \(P_{fi}\), which may produce more matched nodes, or (b) the \(i\)-th bit of \(fc_{j, \Delta}\) and \(tc\) are both 1, i.e., balls with \(tc\) already match with \(P_{fi}\), though there are no edge/node deletions on \(P_{fi}\).

**Example 8:** Consider the input and auxiliary structures in Example 7 and BF in Fig. 3.

(1) \(\Delta P_1\) comes with a unit edge deletion \(\delta_1 = (SD, ST)^{-}\) on \(P_{f1}\), and all four \(fc\) in BF are updated from \(fc(1, 1)\) to \(fc_{1, \Delta}(1, 0)\), as shown in the second column of BF in Fig. 3(b).

IdABall identifies ball \(G(P_{PM, 2})\) with \(tc(1, 1)\) and \(G(P_{PM, 2})\) with \(tc(1, 1)\) as AffBs, since \(tc(1, 1) \& fc_{1, \Delta}(1, 0) = fc_{1, \Delta}(1, 0)\) and \(tc(1, 0) \& fc_{1, \Delta}(1, 0) = fc_{1, \Delta}(1, 0)\). Then IdABall resets the two corresponding filtering codes in BF to \((1, 1)\).

(2) Consider another case when \(\Delta P_2\) comes with \(\delta_2\), where \(\delta_1\) is same as above and \(\delta_2 = (BA, UD)^{-}\). BF is updated as shown in the second column of BF in Fig. 3(c), and IdABall identifies the same AffBs as above.

The correctness of IdABall is ensured by the following.

**Proposition 8:** For any ball \(G[v, r]\) in \(G\), if there exists a perfect subgraph of \(P \oplus \Delta P\) in \(G[v, r]\), then \(G[v, r]\) must be
an affected ball produced by procedure \text{IdABall}.

**Lazy update policy.** To reduce computation, \text{dynamicP} only updates the partial relations for \text{AffBs} in \( M(P,G) \) for computing \( L_k(P \oplus \Delta P,G) \). However, those partial relations in the filtered balls also need an update for handling future updates \( \Delta P' \), but definitely become outdated w.r.t. \( P \oplus \Delta P \). Hence, \text{dynamicP} needs a smart policy to maintain those match relations in the filtered balls.

To do this, algorithm \text{dynamicP} maintains the status of all unit updates applied to \( P \) so far, and processes unit updates in \( \Delta P' \) as late as possible, while having no effects on future updates \( \Delta P' \), i.e., a lazy update policy.

Algorithm \text{dynamicP} utilizes auxiliary structure \text{UP} together with the cflag item in \( \text{BS} \). When handling current \( \Delta P' \), for each ball \( G \), \( G[c\text{flag}] \) records the id of the latest processed unit pattern update for \( G \), and is initialized to 0. When future \( \Delta P'' \) comes, for any AffB \( G \) w.r.t. \( \Delta P' \) and any fragment \( P_{f_i} \), \text{dynamicP} computes \( M(P_{f_i} \oplus \Delta P_{f_i},G) \) based on \( M(P_{f_i},G) \) by procedure \text{IncMatch} (to be shown shortly), where \( \Delta P_{f_i} \) consists of the unit updates stored in \( T(P_{f_i}) \) whose ids are larger than \( G[c\text{flag}] \) in \( \text{BS} \).

**Example 9:** Continue Example \ref{Example:patEIns}. (1) Balls \( G[\text{PM}_1,2] \) and \( G[\text{PM}_2,2] \) are \text{AffBs}, and \text{UP} is shown in Fig. \ref{fig:patEIns}(b)

(a) \text{UP} is updated w.r.t. \( \Delta P_1 = \{\delta_1\} \). \text{dynamicP} updates the partial relations for \( P_{f_2} \) w.r.t. \( \delta_1 \) in the two balls, and sets their cflag in \( \text{BS} \) to \( \delta_1 \), as the status shown in Fig. \ref{fig:patEIns}(a).

(b) Afterwards, \( \Delta P_2 \) with an edge insertion \( \delta_2 = (\text{BA}, \text{UD})^+ \) comes. \text{IdABall} updates \( \text{BF} \) and \text{UP} as shown in Fig. \ref{fig:patEIns}(b) and identifies balls with \( \{1,1\} \) as \text{AffBs}, e.g., \( G[\text{PM}_1,2] \).

(c) Finally, \( \Delta P_3 \) with a node deletion \( \delta_3 = (\text{UD})^- \) comes. \text{IdABall} identifies \( \{1,1\} \), \( \{0,1\} \), and \( \{0,0\} \) as \text{AffBs}. Take ball \( G[\text{BA}_3,2] \) for example, which is the first time identified as an \text{AffB}. By referring to \text{UP}, \text{dynamicP} updates the partial relations for \( P_{f_1} \) w.r.t. \( \{\delta_2, \delta_3\} \), and for \( P_{f_2} \) w.r.t. \( \{\delta_1\} \).

In the case when \( \Delta P'_{f_i} \) contains multiple updates, \( \text{BF} \) and \text{UP} are updated accordingly as shown in Fig. \ref{fig:patEIns}(c).

(ii) Updating Fragment-Ball matches. We then update the partial match relations for AffBs in \( M(P,G) \) w.r.t. \( \Delta P' \), by procedure \text{IncMatch}.

**Procedure \text{IncMatch}**. Given \( h\)-fragmentation \( \mathcal{P}_h \) of \( P,G \), \( M(P,G), \Delta P \), \text{UP} and AffBs w.r.t. \( \Delta P \). \text{IncMatch} updates \( M(P_{f_i},G) \) to \( M(P_{f_i} \oplus \Delta P_{f_i},G) \) in \( M(P,G) \) for each fragment \( P_{f_i} \) and each AffB \( G \). Recall that \( \Delta P_{f_i} \) consists of unprocessed unit updates accumulated in \( \text{UP} \) applied to \( P_{f_i} \).

We show how to update \( M(P_{f_i},G) \) in different cases.

(1) \textbf{There exist edge/node deletions in } \( \Delta P_{f_i} \). In this case, \text{IncMatch} accesses the AffB \( G[v,r] \) in \( G \). It simply computes the maximum match relations for \( P_{f_i} \oplus \Delta P_{f_i} \) in \( G[v,r] \) by procedure \text{undirSim} in \( O(|\mathcal{P}_{h}(P_{f_i} \oplus \Delta P_{f_i} \cap G[v,r])|) \) time.

(2) \textbf{No edge/node deletions in } \( \Delta P_{f_i} \). \text{IncMatch} processes updates of the same type together in this case as follows.

(i) Capacity changes in \( \Delta P_{f_i} \) or updates on \( C \). In this case, no computation is needed for maintaining partial relations for AffBs at all, i.e., \( M(P_{f_i} \oplus \Delta P_{f_i},G) = M(P_{f_i},G) \). Only a capacity check and an inner ball check in the combination procedure are needed (to be seen immediately).

(ii) Edge insertions in \( \Delta P_{f_i} \). In this case, \text{IncMatch} calls procedure \text{patEIns} to process edge insertions.

---

Figure 5: Procedure \text{patEIns}

**Procedure \text{patEIns}**. Given \( M(P_{f_i},G[v,r]) \) (also represented by \( R(v) \)), \( G[v,r] \) and an edge insertion \( \delta = (u,u')^+ \), \text{patEIns} computes \( M(P_{f_i} \oplus \delta, G[v,r]) \) incrementally, as shown in Fig. \ref{fig:patEIns} along the same lines as for data incremental graph simulation \[\text{patEIns} \] first finds the directly affected data nodes that need to be removed from \( R(v) \) due to the edge insertion to \( P_{f_i} \), and pushes them along with the matched pattern nodes into \( \text{RMv} \) (lines 3-8). It then recursively identifies and removes the nodes in \( R(v) \) affected by the previous removed nodes (lines 9-14). The recursive process is executed by utilizing a stack \( \text{RMv} \). If there exists a pattern node \( u \) with empty \( R(u) \), then \( R(v) \) is set to \( \emptyset \) (line 15). Finally, \text{patEIns} returns the updated \( R(v) \) for \( P_{f_i} \) (lines 16-17).

**Example 10:** Consider case (1)-b in Example \ref{Example:patEIns}. Given \( \delta_2 = (\text{BA}, \text{UD})^+ \), and \( M(P_{f_2},G[\text{PM}_1,2]) \), which is composed of nodes \( \text{PM}_1, \text{BA}_1 \) and \( \{\text{UD}_1, \text{UD}_2\} \) mapped to nodes \( \text{PM}, \text{BA} \) and \( \text{UD} \) in \( P_{f_2} \). To compute the updated \( M(P_{f_2} \oplus \delta_2, G[\text{PM}_1,2]) \), \text{patEIns} removes \( \text{UD}_2 \) that is directly affected by \( \delta_2 \), and finds no other nodes need to be removed.

(iii) Node insertions in \( \Delta P_{f_i} \). Node insertions are handled in a similar way as edge insertions, by extending \text{patEIns}.

Given a node insertion \( \delta = (u,(u,u')^+) \), where \( u \) is a newly inserted node, to compute the updated \( M(P_{f_i} \oplus \delta, G[v,r]) \), \text{IncMatch} initially computes the set of nodes \( R(u) \) in \( G[v,r] \) that have the same label with \( u \), and then calls \text{patEIns} \( M(P_{f_i},G[v,r]), G[v,r], (u,u') \) to get the updated result.

**Updating FBM.** After updating \( M(P,G) \), \text{dynamicP} updates FBM for all AffBs, changing the links according to the updated partial relations in \( M(P,G) \), and also updating the cflag item in \( \text{BS} \), which is in \( O(||\text{AffBs}||) \) time.

**Procedure \text{procedure}**. For an AffB \( G[v,r] \), combine invokes \text{patEIns}(\bigcup_{i \in [1:k]} M(P_{f_i},G[v,r]), G[v,r], C \oplus \Delta C) \) to compute the maximum match relations of \( P \oplus \Delta P \) for \( G[v,r] \) incre-
mentally, where $\Delta C$ consists of the edge insertions/deletions in $\Delta P$ applied to the cut edges $C$. It then checks whether the capacity bounds, together with the updates on them, are satisfied. If so, it constructs the perfect subgraph w.r.t. the match relations above. It then checks the inner balls together with the capacity bounds, and finally returns the list of top-$k$ perfect subgraphs $L_k(P \oplus \Delta P, G)$.

Example 11: Continue Example 8(1), after dynamicP updates partial relations for AffBs w.r.t. $\Delta P$, balls $\hat{G}[PM]_i, \hat{G}[PM_2]_i$ and $\hat{G}[BA_2]_i$ enter the combination process. (1) For $\hat{G}[PM]_i$ and $\hat{G}[PM_2]_i$, as $C \oplus \Delta C \subseteq \{PM, SA\}$, combine finds that there is an $SA_i$ (resp. $PM_i$) connecting to $PM_i$ (resp. $SA_i$), and the capacity bounds are satisfied. For inner balls, based on above results, combine finds that no perfect subgraphs reside in $G[PM]_i$ and $G[PM_2]_i$. Hence it returns the above two perfect subgraphs in two balls. (2) For $\hat{G}[BA_2]_i$, combine finds no $SA_i$ connecting to $PM_i$, and vice versa. Hence, no sensible matches are found.

(IV) Early return optimization technique. We propose an optimization technique for dynamicP to further speed-up the incremental computations, by making use of the top-$k$ semantics. We first define early return for incremental top-$k$ algorithms, analogous to early termination for batch top-$k$ algorithms [8].

Early return. An algorithm has the early return property, if for pattern $P$ with updates $\Delta P$ and for any data graph $G$, it outputs $L_k(P \oplus \Delta P, G)$ as early as possible without the need to update match relations for every AffBs, while the updates can be executed in background.

Proposition 9: There exists an algorithm for the dynamic top-$k$ team formation problem with early return property. □

We prove dynamicP retains the early return property. Recall the density based filtering optimization for algorithm batch in Section 3. dynamicP also utilizes density upper bounds for pruning a portion of AffBs. More specifically, given $P$ and $G$, dynamicP maintains the density upper bound for each ball in the $den$ item in $BS_i$, i.e., $\hat{G}[den]$, calculated according to Lemma 3. Thus, given $\Delta P$, if the top-$k$ densest perfect subgraphs found so far are denser than the density upper bound of the remaining AffBs, dynamicP outputs the current top-$k$ densest perfect subgraphs as $L_k(P \oplus \Delta P, G)$, while continuing updating $M(P, G)$ in AffBs in background.

Note that the early return optimization is effective for pattern updates, but not for data updates and the case when $\Delta P$ contains node insertions with new labels (expertise).

(V) The complete algorithm for pattern updates. Given $M(P, G)$, FBM, BF and UP, for pattern update $\Delta P$, algorithm dynamicP computes the top-$k$ perfect subgraphs for $P \oplus \Delta P$ in $G$ with early return property, and maintains auxiliary structures simultaneously by invoking procedure IdABall, IncMatch and combine one by one.

Algorithm dynamicP. It works as follows, as shown in Fig. 4. For each $\Delta P$, dynamicP firstly sets the result list $L_k$ to empty, and identifies AffBs w.r.t. $\Delta P$ by IdABall (lines 1-2). It then sorts AffBs by their density upper bounds $\hat{G}[den]$ in $BS$ in non-ascending order (line 3), and accesses AffBs sequentially by this order (lines 4-10). Whenever it comes to next AffB $\hat{G}[v, r]$, it firstly checks whether there are already $k$ perfect subgraphs found in $L_k$, and moreover, the density of the $k$th (smallest) perfect subgraph in $L_k$ is larger than $\hat{G}[v, r][den]$ (line 5). If so, dynamicP immediately outputs $L_k$ as final results (line 6), and then continues to update $M(P, G)$ for those AffBs in background by IncMatch (line 7); Otherwise, dynamicP updates the partial relations and combines them by combine to get the set of perfect subgraphs $S_G$, in $G[v, r]$ and its inner balls (lines 7-8). It then inserts the set of perfect subgraphs in $S_{G_i}$ into $L_k$ (line 9).

Correctness & complexity analysis. The correctness of dynamicP is assured by the correctness of IdABall (Proposition 5), IncMatch, combine and early return property (Lemma 3). dynamicP is in $O(|L_k|_k \cdot \sum_{i \in \{1, h\}} |M(P_i, G)| + |rM(P_i, \Delta P_i)|) + |r \cdot P \oplus \Delta P|\cdot |\text{AffBs}|\cdot |\Delta P|$ time w.r.t. $\Delta P$, while $r$ is small, i.e., 2 or 3 (See full version 1).

5.3 Dealing with Data Updates

We next propose dynamicG to handle $\Delta G$, following the framework in Section 4.2. Given auxiliary structures $M(P, G)$ and FBM, we put together procedures IdABall, IncMatch and combine for computing match results for $P$ in $G \oplus \Delta G$. As procedures IncMatch and combine handle $\Delta G$ basically the same as $\Delta P$, so we mainly show how IdABall identifies AffBs w.r.t. $\Delta G$.

Procedure IdABall. Given $G, \Delta G$, and FBM, IdABall identifies AffBs according to the lemma as follows.

Lemma 10: A ball $\hat{G}[v, r]$ with center node $v$ in $G$ is identified as an AffB w.r.t. $\Delta G$ and FBM,

1. for some unit data update $\delta$ of $\Delta G$, where (a) $\delta$ is an edge insertion/deletion, $(w_1, w_2)^+/(w_1, w_2)^-$ and $v$ is in both $\hat{G}[w_1, r]$ and $\hat{G}[w_2, r]$ or (b) $\delta$ is a node insertion/deletion, $(w, (v, w'))^+//(w)^-$ and $v$ is in $\hat{G}[w, r]$; or
2. when $\hat{G}[v, r]$ has type code $(1, \ldots, 1)$ in FB.

We say a ball which satisfies condition (1) is a structural affected ball, i.e., the structure of the ball is changed due to the exertion of some updates in $\Delta G$.

Proposition 11: Given $P, G$ and $\Delta G$, if there is a perfect subgraph for $P$ in ball $G \oplus \Delta G[v, r]$ of $G \oplus \Delta G$, then $\hat{G}[v, r]$ must be an affected ball produced by procedure IdABall.

Different from pattern updates, procedure IncMatch recomputes partial match relations in $M(P, G)$ for each pattern fragment of $P$ in each structural affected ball; and no computation is needed for AffBs that only satisfy condition (2) in Lemma 10. Procedure combine combines the partial
We used two real-life graphs.

### 6.1 Experimental Settings

w.r.t. dynamic and (c) simultaneous pattern and data updates, (3) single sets of (a) pattern updates, (b) data updates, w.r.t. \( P \)ous \( \Delta G \) auxiliary structures for continuously coming \( \Delta G \)ing on \( \{ \)performance of (1) batch procedures \( \Delta P \) is determined by \( \Delta P \) ∗ of (1, 1) in FBM as AffBs, i.e., \( G[PM_2, 2] \), while filtering out all other balls. □

**Algorithm dynamicG.** Given \( \hat{M}(P, G) \), FBM and data updates \( \Delta G \), dynamicG computes the match results for \( P \) in \( G \oplus \Delta G \), and maintains auxiliary structures by invoking procedures IdaBall, IncMatch and combine sequentially.

**Correctness & complexity analyses.** The correctness of \( \text{dynamicG} \) w.r.t. \( \Delta G \) follows from Proposition 11 and the correctness of \( \text{IncMatch} \) and combine. dynamicG is overall in \( O(\sum_{G \in \text{AffBs}} |M(P, G \oplus \Delta G)| + |P|(|G| + |\Delta G|)) \) time w.r.t. \( \Delta G \); while \( r \) is small, i.e., 2 or 3 (See [1]).

### 5.4 Unifying Pattern and Data Updates

We are now ready to provide algorithm dynamic, integrating dynamicP and dynamicG, presented in Sections 5.2 and 5.3 respectively, to process continuous pattern and data updates, separately and simultaneously.

**Algorithm dynamic** is able to handle simultaneous \( \Delta P \) and \( \Delta G \), because of the consistency in: (1) the processes for handling \( \Delta P \) and \( \Delta G \), which follow the same steps in Section 4.2 (auxiliary data structures for supporting \( \Delta P \) and \( \Delta G \)); and (3) the combination procedures, which suffice to support simultaneous pattern and data updates.

Observe that dynamic can handle continuously simultaneous \( \Delta P \) and \( \Delta G \), as dynamic incrementally maintains the auxiliary structures for continuously coming \( \Delta P \) and \( \Delta G \).

**Remark.** Note that the running time of dynamicP and dynamicG is determined by \{P, \( \Delta P \), \( \hat{M}(P, G) \), AffBs\} and \{P, \( \Delta G \), \( \hat{M}(P, G) \), AffBs\}, respectively, not directly depending on \( G \). From this, we complete the proof of Theorem 7.

## 6. EXPERIMENTAL STUDY

We conducted four sets of experiments to evaluate the performance of (1) batch for the top-k team formation problem, (2) dynamic for the dynamic top-k team formation problem w.r.t. single sets of (a) pattern updates, (b) data updates, and (c) simultaneous pattern and data updates, (3) dynamic w.r.t. continuous sets of pattern and data updates, and (4) the extra space cost of auxiliary structures used by dynamic.

### 6.1 Experimental Settings

We used the following real-life and synthetic datasets.

**Real-life graphs.** We used two real-life graphs.

1. **CITATION** [4] contains 1.39M paper nodes and 3.02M paper-paper citation edges. We used its undirected version, where edges indicate the relevance relationship, and generated 200 labels based on phrase clustering of paper titles.

2. **YOUTUBE** [5] contains 2.03M video nodes and 12.2M edges, which represent recommendations between two videos. We used the undirected version, and generated 400 labels based on the built-in categories and ages of videos.

**Synthetic graph generator.** We generated synthetic graphs (SYNTHETIC) with community structures as existed in real-life, by adopting the LFR-benchmark graph model [21]. It is controlled by three parameters: the number \( n \) of nodes, the average degree \( d \) of nodes, and the number \( l \) of node labels.

**Pattern generator.** We implemented a generator to produce pattern graphs, controlled by 4 parameters: the number of nodes \( |V_P| \), the number of edges \( |E_P| \), the label \( l_P \) for each node from an alphabet of labels in the corresponding data graphs, and the capacity bound \( f_P \) for each node.

**Algorithms.** We implemented the following algorithms, all in C++: (1) algorithm batch for kTF, (2) incremental algorithm dynamic for kDTF, (3) three compared top-k team formation algorithms minDia, minSum and denAlk, where (a) minDia is to minimize the team diameter [23], which is firstly proposed for the team formation problem, (b) minSum is to minimize the sum of all-pair shortest distances of teams, and (c) denAlk is to maximize the team density [13], which has the same goal with our algorithms. Most of the algorithms for kTF, including minDia and denAlk, only compute the best team, while minSum is able to find top-k teams in polynomial time, which is an adaption of Lawler’s procedure [20]. Based on this, we extend minDia and denAlk to find top-k teams in polynomial time.

We used a PC with Intel Core i5-4570 CPU and 16GB of memory. We randomly generated 3 sets of input and repeated 5 times for each. The average is reported here.

## 6.2 Experimental Results

We present our findings. In all the experiments, we set \( k = 10, r = 2, h = 3, (|V_P|, |E_P|) \) to be (10,12), and capacity bounds to be [1,10] by default. When generating synthetic graphs, we fixed \( n = 10^5 \), \( d = 10 \) and \( l = 200 \). All the findings on YOUTUBE are reported in the full version [4].

**Exp-1: Efficiency of batch.** We firstly evaluated the efficiency of batch vs. minDia, minSum and denAlk. We generated pattern graphs for batch, and the corresponding queries (labels requirements) for minDia, minSum and denAlk.

Algorithms minDia, minSum and denAlk do not scale well on large graphs. Indeed, (1) minDia and minSum took more than 8 hours to finish their preprocessing, i.e., computing all-pair-shortest-paths; and (2) denAlk took more than 24 hours even when \( k = 1 \) on CITATION. By contrast, batch took around 100 seconds on CITATION by default settings. Hence, we report the effectiveness of these algorithms on a sampled data graph with 10,000 nodes on CITATION only.

**Exp-2: Effectiveness of batch.** We then evaluated the effectiveness of batch vs. minDia, minSum and denAlk by evaluating the quality of matches returned by them.

To evaluate the quality of teams found by the above four algorithms for kTF, we defined four quality measures. Consider a matched subgraph \( G_S \) and pattern \( P(V_P, E_P) \).

(a) **[Diameter]:** the diameter of \( G_S \).

(b) **[Density]:** the density of \( G_S \).

(c) **[Node satisfiability]:** \( \eta_l(G_S, P) = |\text{sat}_l(G_S, P)|/|V_P| \), where \( \text{sat}_l(G_S, P) \) is the number of nodes in \( P \) that are satisfied by \( G_S \), in which we say a pattern node \( u \) is satisfied by \( G_S \) if there are a set \( V_u \) of nodes in \( G_S \) that match \( u \) and moreover, \( V_u \) satisfies the capacity constraints on \( u \).
Intuitively, \( \min Dia \) minimizing team densities, are larger than though are smaller than \( \den Alk \). Edge and node satisfiability, and pertains a good team collaboration compatibility \( w.r.t. \) diameter and density.

Exp-3: Efficiency of dynamic for single set of updates.

We evaluated the efficiency of algorithm dynamic for processing one set of pattern updates, data updates and simultaneous pattern and data updates vs. algorithm batch on Citation and Synthetic, respectively.

(d) [Edge satisfiability]: \( \eta_E(G_S, P) = \# \text{sat}_E(G_S, P) / |E_P| \), where \( \# \text{sat}_E(G_S, P) \) is the number of edges in \( P \) satisfied by \( G_S \), in which we say an edge \((u_1, u_2)\) is satisfied by \( G_S \) if for each \( v_1 \in G_S \) that matches \( u_1 \), there exists \((v_1, v_1')\) in \( G_S \) so that \( v_1' \) matches \( u_2 \), and for each \( v_2 \in G_S \) that matches \( u_2 \), there exists \((v_2, v_2')\) in \( G_S \) such that \( v_2' \) matches \( u_1 \).

Note that (a) and (b) are two traditional quality measures utilized by existing team formation algorithms [30, 31]. Intuitively, \( \eta_E(G_S, P) \) (resp. \( \eta_E(G_S, P) \)) measures how well \( G_S \) meets the node capacity requirements (resp. structural constraints) in \( P \), and their values fall in \([0, 1]\).

(i) Impacts of \(|V_P|\). Varying the number \(|V_P|\) of nodes in \( P \) from 4 to 16, we took the average value of top-\( k \) teams found by batch, \( \min Dia \), \( \min Sum \) and \( \den Alk \) \( w.r.t. \) four quality measures. The results are reported in Figures 7(a)-7(d).

Observe the following. (1) The diameters of teams found by batch are comparable to those of \( \min Dia \) and \( \min Sum \), which are in particularly designed to minimize the diameters, as shown in Fig. 7(a). This is ensured by the use of balls in batch. (2) The densities of teams found by batch, though are smaller than \( \den Alk \) which is specialized for maximizing team densities, are larger than \( \min Dia \) and \( \min Sum \), as in Fig. 7(b). (3) The node satisfiability of teams found by batch is much higher than \( \min Dia \), \( \min Sum \) and \( \den Alk \), e.g., 1.0 vs. no larger than 0.2 in all cases as in Fig. 7(c). (4) The teams found by batch come with a higher edge satisfiability , e.g., 1.0 in all cases, compared to smaller than 0.6 by \( \min Dia \), \( \min Sum \) and \( \den Alk \), as shown in Fig. 7(d).

(ii) Impacts of \( k \). Varying \( k \) from 1 to 20, we report the results in Figures 7(e)-7(h). Observe that the quality of teams found by the four algorithms shows the same rule as varying \(|V_P|\), and the quality is not sensitive to \( k \), a desirable property when top-\( k \) semantics is concerned.

These verify that batch can effectively preserve structural and capacity constraints for top-\( k \) team formation \( w.r.t. \) edge and node satisfiability, and pertains a good team collaboration compatibility \( w.r.t. \) diameter and density.

(i) Pattern updates. We fixed \(|V_P|, |E_P|\) to be (10, 12), and varied the number \(|\Delta P|\) of unit updates from 1 to 11, corresponding to 4.5% to 49.5% in Figs. 8(a), 8(b), 8(c) and 8(d) which show the results when \( \Delta P \) contains (edge and node) deletions, (edge and node) insertions, capacity changes and hybrid pattern updates (5 types) respectively, while keeping the proportion for each type equal.

We find the following. (1) dynamic outperforms batch even when deletions are no more than 40.5% on Citation and 49.5% on Synthetic; dynamic consistently does better than batch due to the early-return strategy. (2) dynamic improves batch to a large extent when only processes insertions and capacity changes. (3) For the same \(|\Delta P|\), dynamic needs less time to process insertions than deletions. (4) When processes hybrid pattern updates, dynamic outperforms batch when changes are no more than (31.5%, 40.5%) on (CITATION, SYNTHETIC); It is because all balls are identified as AffBs when pattern updates accumulate to a certain extent.

(ii) Data updates. For (edge and node) deletions (resp. insertions) on datasets, e.g., Citation with \(|G| = 4.4M\), we varied \(|\Delta G|\) from 4.4M to 2.22M (resp. from 3.05M to 4.4M) in 4.5% decrements (resp. 4% increments) by randomly picking a subset of nodes and edges and removing from \( G \) (resp. inserting into \( G \)). For hybrid data updates (4 types), we randomly sampled a subgraph \( G_s \) and removed from \( G \), obtaining the initial \( G \). We varied \(|\Delta G|\) by firstly removing a subset of nodes and edges from \( G \) and then inserting a subset of nodes and edges from \( G_s \) into \( G \), in total 4% updates. The results are shown in Figures 8(c), 8(f) and 8(g).

We find the following. (1) dynamic outperforms batch when insertions are no more than 28% and 32% on Citation and Synthetic (resp. 40.5% and 45% for deletions). (2) For the same \(|\Delta G|\), dynamic needs less time to process deletions than insertions. (3) We have conducted a survey: the user increment on Facebook [1] and Twitter [2] daily reaches 1.23% and 2.47%. Therefore, dynamic is able to handle the increments accumulated in dozens of days on Facebook and Twitter at a high efficiency. (4) dynamic outperforms batch when hybrid data updates are no more than 32% and 36% on Citation and Synthetic, respectively.

(iii) Simultaneous pattern and data updates. Varying the number of hybrid pattern updates from 1 to 7 and the
amount of hybrid data updates from 4% to 28% together, corresponding to (4.5%, 4%) to (31.5%, 28%) for $\Delta P, \Delta G$ in Fig. 8(b). We find that dynamic outperforms batch when $(\Delta P, \Delta G)$ is no more than (22.5%, 20%) and (27%, 24%) on Citation and Synthetic, respectively.

**Exp-4: Efficiency of dynamic for continuous sets of updates.** We evaluated dynamic for a serial sets of pattern updates, data updates and simultaneous pattern and data updates vs. batch on Citation and Synthetic.

**i) Pattern updates.** We generated 5 sets of hybrid pattern updates, varying the number of updates in each set from 1 to 7. We tested the average time took by dynamic to finish all these sets one by one. The results are reported in Fig. 8(i)

Recall that dynamic adopts a lazy update policy, which definitely affects the processing time of next updates. However, we find dynamic outperforms batch w.r.t. average time, when the amount of hybrid pattern updates in each set is no more than (27%, 31.5%) on (Citation, Synthetic). This verifies the effectiveness of our lazy update policy.

**ii) Data updates.** The setting is same as above. Varying the amount of hybrid data updates in each set from 4% to 28%, the results are reported in Fig. 8(j) We find that dynamic outperforms batch when hybrid data updates are no more than (24%, 28%) on (Citation, Synthetic).

**iii) Simultaneous pattern and data updates.** Using the same setting and varying the simultaneous pattern and data updates $(\Delta P, \Delta G)$ from (4.5%, 4%) to (31.5%, 28%) in Fig. 8(k) We find that dynamic outperforms batch when updates in each set are no more than (18%, 16%) and (22.5%, 20%) on Citation and Synthetic, respectively.

**Exp-5: Physical storage of auxiliary structures.** As shown in Fig. 8(l) the incremental algorithm dynamic takes (25MB, 130MB) extra space to store all its auxiliary structures on (Citation, Synthetic), while they need (36MB, 482MB) space to store themselves. That is, the auxiliary structures are light-weight, and only take (69.4%, 26.9%) extra space compared with the original datasets.

**Summary.** From these tests, we find the following.

1. Our graph pattern matching approach is effective at capturing the practical requirements of top-k team formation.
2. Our batch algorithm for top-k team formation is efficient, e.g., it only took 116s when $|V| = 1.39M$ and $|V| = 10$.
3. Our incremental algorithm for dynamic top-k team formation is able to process continuous pattern and data updates, separately and simultaneously, and it is more promising than its batch counterpart, even (a) when changes are 36% for pattern updates, 34% for data updates, and (25%, 22%) for simultaneous pattern and data updates on average, and (b) when 29% for continuous pattern updates, 26% for continuous data updates and (20%, 18%) for continuously simultaneous pattern and data updates on average.

**7. CONCLUSION**

We have introduced a graph pattern matching approach for (dynamic) top-k team formation problem. We have proposed team simulation, based on which we have developed a batch algorithm for top-k team formation. We have also developed a unified incremental algorithm to handle continuous pattern and data updates, separately and simultaneously. We have experimentally verified the effectiveness and efficiency of the batch and incremental algorithms.

A couple of topics are targeted for future work. First, an interesting topic is to develop distributed algorithms for top-k team formation. Second, the study of dynamic algorithms...
for query updates is in its infancy, and hence, an important topic is to develop such algorithms for various problems.
