Abstract. In this paper, we discuss the influence of meteorological effects on the data of the ground installation CARPET, which is a detector of the charged component of secondary cosmic rays (CRs). This device is designed in the P.N. Lebedev Physical Institute (LPI, Moscow, Russia) and installed at the Dolgoprudny scientific station (Dolgoprudny, Moscow region; 55.56° N, 37.3° E; geomagnetic cutoff rigidity \( R_c = 2.12 \text{ GV} \)) in 2017. Based on the data obtained in 2019–2020, the barometric and temperature correction coefficients for the CARPET installation were determined. The barometric coefficient was calculated from the data of the barometric pressure sensor included in the installation. To determine the temperature effect, we used the data of upper-air sounding of the atmosphere obtained by the Federal State Budgetary Institution “Central Aerological Observatory” (CAO), also located in Dolgoprudny. Upper-air sounds launch twice a day and can reach an altitude of more than 30 km.

1 Introduction

The basis of the CARPET installation (Fig. 1) is the STS-6 gas-discharge Geiger–Müller counters, combined in 12 detector blocks of 10 counters each. The detector block consists of two layers: five upper and five lower counters, separated with an aluminum absorber (filter) 7 mm thick. Experimental data are recorded using three channels with a time resolution of 1 ms. The first channel (UP) corresponds to the integral count rate of charged particles passing through the top layer of 60 counters. The second channel (LOW) corresponds to the integral count of charged particles passing through the bottom layer of 60 counters. Particles simultaneously registered by both the upper and lower counters, i.e., passed through the filter, are registered in the coincidence channel – TEL.

In addition, there is a channel of auxiliary information (“telemetry”), which consists of the data on atmospheric pressure, temperature, and supply voltages.

The CARPET installation detects particles of the following energies: in the UP and the LOW channels there are electrons and positrons with energies \( E > 200 \text{ keV} \), protons with \( E > 5 \text{ MeV} \), muons with \( E > 1.5 \text{ MeV} \) (efficiency \( \sim 100 \% \)), and photons with \( E > 20 \text{ keV} \) (efficiency \( < 1 \% \)). The TEL coincidence channel registers more energetic particles: electrons with energies \( E > 5 \text{ MeV} \), protons with \( E > 30 \text{ MeV} \), and muons with \( E > 15.5 \text{ MeV} \). Detailed information on the principles of CARPET operation was given previously (Philippov et al., 2020a). In addition to the CARPET installations, there are two other types of detectors which are also integrated to the network: “neutron detector” (ND) installations (Philippov et al., 2020c), which are sensitive to the neu-
2 Instrumentation and data analysis

Ground-based CARPET installations detect secondary charged particles, mainly muons, generated in the interaction of primary CRs with nuclei in the atmosphere. Muons are not nuclear-active particles (such as protons, neutrons, and also charged pions and kaons) and lose energy for the excitation and ionization of air atoms. Ionization losses depend on the amount of matter above the detector; therefore, the barometric effect must be taken into account. The altitude of muon generation in the $\pi/K$ decays is temperature dependent; therefore the temperature effect in the atmosphere must be taken into account (Dorman, 1972, 2004, 2006).

2.1 Barometric effect

The barometric effect can be determined through variations in atmospheric pressure at the level of CR registration (Eq. 1):

$$\left( \frac{\Delta N}{N_0} \right)_{\rho} \equiv \beta \Delta P,$$

(1)

where $\left( \frac{\Delta N}{N_0} \right)_{\rho}$ is the relative variation of the count rate of the CARPET installation; $\Delta N = N - N_0$; $\Delta P = P - P_0$; $N_0$ is the average (standard) count rate [pulses/h] for the period of measurements; $N$ is the current count rate [pulses/h]; $P_0$ is the average (standard) ground atmospheric pressure [hPa] for the period of measurements; $P$ is the current atmospheric pressure [hPa].

According to the data for 2019, hourly averaged average count rate and atmospheric pressure for the CARPET-MOSCOW installation $N_0 = 53,667$ pulses/h, mean square deviation of the count rate $\sigma_N = 2187$ pulses/h; $P_0 = 988.7$ hPa, and mean square deviation of the atmospheric pressure $\sigma_P = 9.8$ hPa.

For calculating the barometric coefficient $\beta$, it is necessary to determine the linear relationship between $\left( \frac{\Delta N}{N_0} \right)_{\rho}$ and $\Delta P$ (Fig. 2). The barometric coefficient $\beta$ for the CARPET-MOSCOW installation (which is located at the Dolgoprudny Scientific Station of the Lebedev Physical Institute RAS, Moscow region) is determined for the data of June 2019 (during this period there were no significant geomagnetic, solar, and temperature disturbances): $\beta = -0.1861 \pm 0.0025$ %/hPa; coefficient of determination $R^2 = 0.8975$. Using Eq. (1), we obtain pressure-corrected data:

$$N_{PC} = N - \beta N_0 \Delta P,$$

(2)

where $N_{PC}$ is the average pressure-corrected count rate [impulses/h] of the CARPET installation.

To prove that secondary CR variations associated with barometric effect are more significant than variations of primary CR variations, we use pressure-corrected data of the Moscow neutron monitor (http://cr0.izmiran.ru/mosc/, last...
access: 5 September 2021). The average count rate according to the data of 2019 is $\bar{N}_{nm} = 9699$ pulses/min and $\sigma_{nm} = 66$ pulses/min.

Figure 3 shows neutron monitor count rate variations on the data of 2019. The black horizontal line is the average count rate [pulses/min] according to the annual data. Black vertical dashed lines are the boundaries of the months. The names of the month are signed at the bottom. The standard deviations for the data of each month are shown at the top. The relative magnitude of the effect determined by the variations in primary CRs over a given period of time can be estimated by the ratio $\sigma_{nm}/\bar{N}_{nm} = 0.007$ (0.7 %).

Magnitude of the barometric effect of the CARPET-MOSCOW can be estimated as $\beta \cdot \sigma_P = 0.018$ (1.8 %), which is more than 2 times higher than variations of primary CRs. Therefore, the barometric effect is significant for the CARPET installations and must be taken into account in the further data processing.

2.2 Temperature effect

The muon component of secondary CRs is characterized by a significant temperature effect (Yanke et al., 2011). To correct the CR measurements for this effect, it is necessary to carry out temperature measurements in the atmosphere close to the location of the CR instrument. The temperature effect has two components: negative and positive. The negative temperature effect is associated with a decrease in muon fluxes during heating and expansion of the atmosphere. The positive temperature effect is associated with the appearance of additional muons, due to a decrease in the density of the atmosphere and, in connection with this, a decrease in the probability of interaction of charged pions and kaons with air nuclei. As a consequence, the probability of decays of charged pions and kaons and the appearance of additional muons increases. These two effects (positive and negative) are competitive (Dorman, 1972, 2004, 2006; Yanke et al., 2011).

To estimate the temperature effect, we used data of the TEL channel of the CARPET-MOSCOW installation for 2019–2020. The altitude profiles of temperature and pressure were determined from the experimental data of the Central Aerological Observatory (CAO; Dolgoprudny).

The temperature effect was determined in two ways: based on the effective generation level method and the integral method (Dmitrieva et al., 2013; Ganeva et al., 2013; Zazyan et al., 2015).

2.2.1 Effective generation level method

To eliminate the barometric effect, original data (Fig. 4a) were processed according to Eq. (1) (Fig. 4b). The barometric correction mainly compensates for the daily variations in the count rate.

The effective generation rate method is based on the assumption that muons are mainly generated at a certain isobaric level, which is 100 hPa (Dmitrieva et al., 2013). The height $H$ of this level depends on the atmospheric temperature. The deviation of the count rate of the installation, therefore, depends on the change in the height of the generation level $\Delta H$ and the change in the temperature of this layer of air:

$$\left(\frac{\Delta N}{N_0}\right)_T = \alpha_H \Delta H + \alpha_T \Delta T,$$

(3)
where \( \left( \frac{\Delta N}{N_0} \right)_T \) is the count rate relative variations of the CARPET installation; \( \Delta H \) is absolute deviation of the effective generation level [km]; \( \alpha_H \) is negative temperature coefficient [%/km]; \( \Delta T \) is absolute temperature deviation at the level of effective generation [°C]; \( \alpha_T \) is positive temperature coefficient [%/°C].

Upper-air meteorological sondes are launched twice a day, at 11:30 and 23:30 UTC (Kochin et al., 2021). The picture of a typical MRZ-3AK1 sonde is presented in Fig. 5. Flights last, on average, about 1.5 h. Therefore, from the available data of the CARPET-MOSCOW installation, samples were made of hourly data from 12:00 to 13:00 and 00:00 to 01:00 UTC.

To calculate the contribution of the negative component of the temperature effect, we define the linear relationship between \( \Delta N \) and \( \Delta H \) (Fig. 6), where \( \Delta N = N_{PC} - N_0 \); \( \Delta H = H - H_0 \); \( H_0 \) is the average (standard) height of the level of effective generation [km] for 2019–2020; \( H \) is the current height of the level of effective generation [km].

For the CARPET-MOSCOW installation, \( H_0 = 16.1 \) km and \( \sigma_H = 0.3 \) km. Using the least squares method, we define the approximating line, the slope of which is equal to \( \alpha_H \).

\[
\alpha_H = -4.00684 \pm 0.0652 \text{ [%/km]}; \quad \text{coefficient of determination } R^2 = 0.8191.
\]

The corrected data series (Fig. 4c) is calculated by the following equation:

\[
N_{HPC} = N_{PC} - \alpha_H N_0 \Delta H, \tag{4}
\]

where \( N_{HPC} \) is the count rate [pulses/h] of the CARPET installation with negative temperature effect correction.

To calculate the contribution of the positive component of the temperature effect, we define the linear dependence between \( \Delta N \) and \( \Delta T \) (Fig. 7), where \( \Delta N = N_{HPC} - N_0 \); \( \Delta T = T - T_0 \); \( T_0 \) is the average (standard) temperature at the level of effective generation [°C] for 2019–2020 according to CAO measurements; \( T \) is the current temperature at the level of effective generation [°C]. \( T_0 = -56.9 \) °C, and \( \sigma_T = 6.0 \) °C.

Using the least squares method, we define the approximating line, whose slope is \( \alpha_T \).

\[
\alpha_T = 0.0080 \pm 0.0038 \text{ [%/°C]}; \quad \text{coefficient of determination } R^2 = 0.0049.
\]

As seen in Fig. 7, there is a slight positive temperature effect. Corrected data series is calculated by the following equation (Fig. 4d):

\[
N_{THPC} = N_{HPC} - \alpha_T N_0 \Delta T, \tag{5}
\]

where \( N_{THPC} \) is the count rate [pulses/h] of the CARPET installation with positive temperature effect correction.

### 2.2.2 Integral method

Consider the integrals method for determining the temperature effect:

\[
\left( \frac{\Delta N}{N_0} \right)_T = \int_0^P \alpha(x) \Delta T(x) \, dx, \tag{6}
\]

where \( P \) is the atmospheric pressure at the point of determination of the temperature effect [hPa]; \( \alpha(x) \) is the density of the temperature coefficient [%/°C/hPa]; \( \Delta T(x) \) is the temperature deviation from the average value in the air layer corresponding to the pressure from \( x \) to \( x + dx \).
Figure 4. Count rate variations of the CARPET-MOSCOW installation for the period of 2020–2021: (a) uncorrected data, (b) pressure-corrected data, (c) pressure- and temperature-corrected (negative effect applying the effective generation method) data, (d) pressure- and temperature-corrected (negative and positive effect applying the effective generation method) data, (e) pressure- and temperature-corrected (the integral method) data. Grey lines indicate initial data, and black lines indicate data with averaging by 24 points.
There are 16 isobaric surfaces commonly accepted while analyzing upper-air atmospheric effects: 1000, 925, 850, 700, 500, 400, 300, 250, 200, 150, 100, 70, 50, 30, 20, and 10 hPa. They are also used in observations by CAO. It was decided to exclude the surface of 10 hPa from the calculations, since for this isobaric surface pressure level, the time period 2019–2020 there are only 148 measurements.

Represent Eq. (6) as a sum:

$$\left( \frac{\Delta N}{N_0} \right)_T = \sum_P \alpha(P) \Delta T(P),$$

where $\alpha(P)$ is the temperature coefficient for a given isobaric surface [%/°C]; $\Delta T(P)$ is the deviation of temperature from the average value for a given isobaric surface [°C].

Starting from the first isobaric surface (20 hPa), we will determine the dependence between $\frac{\Delta N}{N_0}$ and $\Delta T$. The corrected data for the first surface are then used to determine the temperature coefficient for the next surface, and so on:

$$N_{i+1} = N_i (1 - \alpha_{i+1} \Delta T_{i+1}),$$

where $\alpha_{i+1}(P)$ is the temperature coefficient of the isobaric surface $i + 1$ [%/°C]; $\Delta T_{i+1}(P)$ is the temperature deviation from the average value for the isobaric surface $i + 1$ [°C]; $N_i$ is the count rate of the CARPET-MOSCOW, with temperature correction along the isobaric surface $i$; $N_{i+1}$ is the count rate of the CARPET-MOSCOW, with temperature correction along the isobaric surface $i + 1$.

The results are shown in Table 1: the first column is the atmospheric pressure on the given surface, the second column is the average temperature according to the data for 2019–2020, the third column is the standard deviation of the temperature, the fourth column is the temperature deviation for the given isobaric surface, and the fifth column is number of measurements (number of launches at which the sound reached the required altitude). Figure 4e shows the count rate of the CARPET-MOSCOW installation, corrected with integral method, according to the data for 2019–2020.

Comparison of Fig. 4c and d shows that the contribution of the positive temperature effect is small. Comparison of Fig. 4d and e demonstrates that the efficiency of data correction using the integral method is worse than using the effective generation method.

We can compare the efficiency of the correction for positive and negative temperature effects by comparing the CARPET-MOSCOW data with the data of a neutron monitor, which is practically not sensitive to the influence of temperature. The correlation coefficient between the pressure-corrected neutron monitor data for the period of 2019–2020 and the CARPET-MOSCOW data corrected for pressure and the negative temperature effect is $R = 0.38$, taking into account that the positive temperature effect is $R = 0.39$. Thus, the contribution of the correction for the positive temperature effect to the results of the CARPET-MOSCOW installation is small.

### 3 Conclusion

This paper describes the CARPET installation, designed for detecting the charged component of secondary CRs. The barometric coefficient was determined using the built-in pressure sensor. The temperature coefficient was determined by two methods using the data of the upper-air sounding. The integral method for determining the temperature effect is the most accurate. However, due to the lack of regular measurements at high altitudes (since not all sounds reach high altitudes), it can be seen that the data processed with this method.
are less accurate. It also shows less correlation with the data of the Moscow neutron monitor. In this connection, it is more optimal to use the method of the effective generation level, since it does not require a complete temperature profile. Also, for the CARPET-MOSCOW installation, it is possible to use only the negative component of the temperature effect, since variations of the count rate have a good \( R^2 = 0.8191 \) correlation with \( \Delta H \).
