ABSTRACT

Flaxseed cake contains cyanogenic glucosides, which can be metabolized into hydrocyanic acid in an animal’s body, leading to asphyxia poisoning in cells. Beta-glucosidase is highly efficient in degrading cyanogenic glucosides. The Cattle may have β-glucosidase-producing strains in the intestinal tract after eating small amounts of flaxseed cake for a long time. This study aimed to isolate a strain from cow dung that produces β-glucosidase with high activity and can significantly reduce the amount of cyanogenic glucosides. We used cow dung as the microflora source and an esculin agar as the selective medium. After screening with 0.05% esculin and 0.01% ferric citrate, we isolated 5 strains producing high amounts of β-glucosidase. In vitro flaxseed cake fermentation was fermented by these 5 strains, in which the strain M-2 exerted the best effect (P < 0.05). The strain M-2 was identified as Lichtheimia ramosa and used as the fermentation strain to optimize the fermentation parameters by a single factor analysis and orthogonal experimental design. The optimum condition was as follows: inoculum size 3%, water content 60%, time 144 h, and temperature 32 °C. Under this condition, the removal rate of cyanogenic glucosides reached 89%, and crude protein increment reached 44%. These results provided a theoretical basis for the removal of cyanogenic glucosides in flaxseed and the comprehensive utilization of flaxseed cake.

1. Introduction

Flax is an annual plant roughly divided into fiber flax, oil flax, and dual-purpose type flax (Gao et al., 2010). The residue obtained after pressing flaxseeds is flaxseed cake. It is widely used in food additives, animal feeds, and crop cultivation, because it is rich in dietary fiber, essential amino acids, and many other active components. However, it’s utilization was limited due to the existence of phytic acid, aminoglycosides, and other anti-nutritional factors, especially cyanogenic glucosides (Ganorkar and Jain, 2013; Russo and Reggiani, 2014). It was only added to the ruminant feed in animal production (Sun, 2010).

Researchers worldwide have made immense efforts to degrade cyanogenic glucosides using varied methods such as poaching, squeezing, solvent-based method, and microwave-based method (Sun and Xu, 2007; Wu et al., 2008; Lan, 2012). However, these methods have certain limitations such as high cost or having chemical residue. As a result, these methods have not been used in industrial production. Studies indicate that the β-glucosidase has a
This study used cow dung as the microcake for a long time. Moreover, the ruminant (cattle) diets without any adverse reactions. There-according to the insert method (Archana et al., 2012). Molecular tics of mycelia and spore were observed under the microscope were incubated on the PDA medium for 72 h, and the characteris-

Proskauer test, fermentation of carbohydrates and alcohol, indole identi-

ber of bacteria capable of degrading gossypol in cottonseed meal and were able to meet feed quality standards after fermentation (Zhu et al., 2010).

The untreated flaxseed cake can be used as a feed supplement in the ruminant (cattle) diets without any adverse reactions. Therefore, it is inferred that cattle may have β-glucosidase-producing strains in the digest tract after they eat small amounts of flaxseed cake for a long time. Moreover, β-glucosidase can degrade esculin into escin, which gives a black color when treated with Fe³⁺ and can be used for screening (Perez et al., 2011; Hyunsu et al., 2017). This study used cow dung as the microflora source and an esculin medium as the selective medium for β-glucosidase-producing strains. After separation, the cultured strains underwent molecular biological identification. The activity of β-glucosidase was deter-

First, the standard curve of para-nitrophenol (pNP) was plotted. The pNP solution (1.0, 2.0, 3.0, 4.0, 5.0, and 6.0 mmol/L) was prepared using acetic acid-sodium acetate buffer (pH 5.0, 0.2 mol/L). The mixture containing 0.1 mL of pNP solution and 0.9 mL of acetic acid—sodium acetate buffer (pH 5.0, 0.2 mol/L) was incubated at 45 °C for 30 min in a water bath. Then, 2 mL of sodium carbonate solution (0.5 mol/L) and 9 mL of distilled water were added. The different concentrations of pNP were reflected by changes in the absorbance at 400 nm.

The isolated cultures were incubated at 37 °C (bacteria) or 28 °C (fungi) and 180 r/min for 72 h. The crude enzyme extract was obtained by centrifuging the liquid mixture at 1,000 × g and 4 °C for 15 min, and the supernatant was collected. The mixture containing 0.1 mL of crude enzyme, 0.2 mL of p-NPG solution (5 mmol/L), and 0.7 mL of acetic acid—sodium acetate buffer (pH 5.0, 0.2 mol/L) was incubated at 45 °C for 30 min in a water bath. The reaction was stopped by adding 2 mL of sodium carbonate solution (0.5 mol/L) and 9 mL of distilled water to the mixture, boiling it for 3 min, and cooling in an ice bath. The pNP concentration was reflected by changes in the absorbance at 400 nm.

One unit of β-glucosidase enzyme activity was determined as the amount of enzyme needed to produce 1 μmol pNP per min using p-NPG as the substrate.

2.2. Strain identification

The isolated bacteria were incubated in the LB liquid medium at 37 °C and 180 r/min for 24 h and observed under a microscope according to the classical Gram staining (Shrivastava, 2011). The isolated bacteria were identified by a series of physiological and biochemical tests according to the common bacterial system identification manual (Dong and Cai 2001), including Voges-Proskauer test, fermentation of carbohydrates and alcohol, indole test, urease test, L-tyrosine hydrolysis test, sodium malonic acid hydrolysis test, and so on. After purification of fungi, the samples were incubated on the PDA medium for 72 h, and the characteristics of mycelia and spore were observed under the microscope according to the insert method (Archana et al., 2012). Molecular identification was performed by a ribosomal DNA (rDNA) internal spacer (16S rDNA or internal transcribed spacer [ITS]) region sequencing using 16S rDNA universal primers: P2, 5'-AGAGTTTGATCATTGCGCTCAG-3'; P3, 5'-GTATCCATTGACAATC-3' (Polz and Cavanaugh, 1998); ITS universal primers: ITS1, 5'-TCCTAGGTGAACCTGCGG-3'; ITS4, 5'-TCTCCGCTTATTGATATGC-3'. The 16S rDNA or ITS was amplified from genomic DNA, purified, sequenced, and analyzed using the Basic Local Alignment Search Tool (BLAST) program from National Center for Biotechnology Information. The polymerase chain reaction procedures were performed as described by Tao et al. (2004). The phylogenetic tree was generated using the Neighbor-Joining Algorithm in the MEGA7.0 software. Then the physiological and biochemical character-

2.4. Screening of the fermentation strain

We weighed 8 g of flaxseed cake into a flask UV sterilization for 1 h fermentation. The initial aerobic fermentation condition was as follows: water content 60%, inoculum concentration 5% (wt/wt), time 6 d, and temperature 37 °C (bacteria) or 28 °C (fungi). The flaxseed cake was fermented and detoxified with the selected strains. After fermentation, the amount of residual cyanogenic glycosides was determined by silver nitrate titration (Ivanov et al., 2012). The cyanogenic glycoside removing effects of each strain were compared, and one fungus with the highest removal rate of cyanogenic glycosides was selected as the fermentation strain. Then, the optimum growth temperature and pH of this fungus was further explored. The dry weight method was used to measure the biomass content (Xu, 2005). The procedures were as follows: 1) the spore suspension (1 × 10⁹/mL, 3 mL) was added to an Erlenmeyer flask containing 47 mL of PDA liquid medium. The mixture was incubated at different temperatures and different pH at 180 r/min for 48 h; 2) the biomass was obtained by centrifuging the cultures at 4,000 × g and 4 °C for 15 min; 3) the sediment was collected, rinsed with distilled water, and centrifuged at 4,000 × g and 4 °C for 15 min, and the supernatant was discarded. This procedure was repeated 3 times. The final sediments were dried in an oven at 80 °C and weighed twice during the drying until there was no difference between 2 times of weighing, and the weight was recorded. The
temperature gradient was set to 22, 24, 26, 28, 30, 32, and 34 °C, and the pH gradient was set to 4, 5, 6, 7, 8, and 9.

2.5. Optimization of fermentation detoxification conditions

The fermentation time, temperature, water content, and inoculation quantity are considered as the key influencing factors in the microbial fermentation of flaxseed cake (Wang, 2007). These 4 factors were selected to determine the optimum process conditions, and the crude protein increment evaluation was used as the index while studying the fermentation process by a single factor analysis and an orthogonal experimental design, which was shown in Table 1 (Yin et al., 2011; Zhou, 2002). Crude protein content was determined by the direct distillation (Wang, 2008).

3. Results

3.1. Screening of β-glucosidase-producing strains and morphological observation

Five strains with larger ratio of black halo diameter to colony diameter (H/C) were isolated after screening using LB-esculin medium and PDA-esculin medium plates. Three strains, named X-1, X-3, X-6, were of bacteria, and 2 strains, named M-1, M-2, were of fungi. The screening results and the morphological characteristics of these strains are shown in Fig. 1: Strain X-1: the bacterium was bacilliform with negative coloring; the surface colonies on medium were circular in shape, creamy-white, moist, and uplifted; and the edge was smooth. Strain X-3: the bacterium was bacilliform with negative coloring; the surface colonies on medium were circular in shape, creamy-white, moist, and uplifted; and the edge was smooth. Strain X-6: the strain was Gram negative and bacilliform with no spores or capsule; the edge was smooth; and the colony was thin, translucent, and white in the center. Strain M-1: the colony was round, white, and irregular edges; the hyphae were fluffy; the hyphae were fissional, and the spores were single or agminated under the microscope. Strain M-2: the colony was round and white with black formation was found on the top of the hyphae; spore cysts were colorless or black, and mostly spherical.

3.2. Identification of microbes

The DNA sequence analysis showed that the nucleotide sequence of X-1 had a 99% similarity with the reported sequence of Citrobacter, the nucleotide sequence of X-3 had a 99% similarity with the reported sequence of Providencia, the nucleotide sequence of X-6 had a 99% similarity with the reported sequence of Proteus, the nucleotide sequence of M-1 had a 99% similarity with the reported sequence of Geotrichum candidum, and the nucleotide sequence of M-2 had a 99% similarity with the reported sequence of Lichtheimia ramosa. All E-values of BLAST were 0.0. The phylogenetic tree was constructed using the Neighbor-Joining Algorithm of the MEGA70 software, and the results are shown in Figs. 2–4. Combined with morphological observation, it was concluded that X-1 was Citrobacter, X-3 was Providencia, X-6 was Proteus, M-1 was G. candidum, and M-2 was L. ramosa. Since the aforementioned 3 bacterial genera contained different taxa, the physiologial and biochemical characteristics of these 3 strains were analyzed. The results are shown in Table 2. The analysis of the results showed that X-1 was Citrobacter freundii, X-3 was Providencia rettgeri, and X-6 was Proteus vulgaris.

3.3. Comparison of enzyme activities of isolated strains

The experimental results indicated that the enzyme activity of β-glucosidase in strain M-1 was 3.54 U/mL which was the highest among all strains, followed by 3.19 U/mL of strain M-2. The enzyme activities of X-1, X-3 and X-6 were 2.45, 2.42 and 2.51 U/mL respectively. Overall, the enzyme production capacity of fungi was higher than that of bacteria (Table 3).

3.4. Screening of the fermentation strain

The analysis showed that the degradation rates of X-1, X-3 and X-6 for cyanogenic glycosides were almost the same as that of the control group. The cyanogenic glycoside removal rates of X-1, X-3 and X-6 were 76.66%, 75.93% and 75.68%, and the cyanogenic glycoside removal rates of M-1 and M-2 were 81.674% and 87.783%, respectively. Virus-free rates were significantly improved compared with that of the control group (Fig. 5). It showed that the optimum growth condition of M-2 is pH 7 and 30 °C (Fig. 6).

3.5. Optimization of fermentation conditions

The result of exploring the fermentation condition showed that the optimal condition for achieving the highest increase in the crude protein content after fermentation was as follows: temperature 32 °C, time 7 d, water content 60%, and inoculation amount 3%. The levels of orthogonal experimental variables were determined according to the aforementioned single factor experimental results. The 4 factors and 3 levels of orthogonal design are shown in Table 1. The results and range analysis are shown in Table 4. The analysis showed that the optimum fermentation condition was temperature 32 °C, time 144 h, water content 60%, and inoculation amount 3%. The primary and secondary order of single factors that affected the crude protein increment were inoculation amount, water content, temperature, and time (Fig. 7).

4. Discussion

Ruminants have a relatively stable microbial ecological balance system and contain rich microbial flora. Zhu et al. (2010) has shown that ruminants formed a tolerance mechanism to cyanogenic glycosides during long-term evolution. In addition, the content of rhodanese in ruminants was significantly higher than that in monogastric animals (Zhao and Wang, 2008). Our findings are consistent with the above studies. In this study, all of the highly productive β-glucosidase strains were isolated from the dung of cows fed flaxseed cake for a long time. This shows that β-glucosidase-producing strains in the intestine of these cows have a higher level of content than that of cows not fed flaxseed cake.

The same result was also found during in vitro fermentation. Before this study, we used dung from cows fed flaxseed cake to ferment flaxseed cake, and found that the removal rate of cyanogenic glycosides of cows fed long-term ferment flaxseed cake was higher than those not fed flaxseed cake. This also confirmed the above point that the intestinal microflora of cows are subjected to long-term domestication of flaxseed cake. In other words, it is likely that β-glucosidase producing strains are present in the gut.
However, this study did not perform genomic analysis of the gut microbes of cows, so this conclusion needs further verification.

Based on these conjectures, we aimed to ferment flaxseed cake in vitro. In fact, we isolated 5 high yield strains of bacteria and fungi that produce β-glucosidase, and successfully screened the strain M-2 with a good fermentation performance. During the screening of fermentation strains, we found that the fermentation effects of M-1 and M-2 are better. It is very likely that bacteria have no advantage in solid fermentation systems. In addition, bacterial metabolism and reproduction require a more stringent nutritional ingredient ratio, and the composition of flaxseed cake is more complex and may not meet the growth requirements of bacteria (Zhai and Yang, 2014). Although X-1, X-3 and X-6 are capable of producing β-glucosidase, they cannot grow in large numbers and thus result in a low removal rate of cyanogenic glucosides. Cyanogenic glycosides are soluble in water. Therefore, even if the degrading bacteria are not added, about 70% of cyanogenic glycoside removal occurs after water invasion treatment for 6 d. Therefore, we also observed a decrease in cyanogenic glycosides in the control group.

Crude protein is one of the main nutritional indicators in feed nutrients, and it is also one of the important indicators for evaluating the nutritional value of feed. It is a general term for

nitrogenous substances in feed, including pure protein and amides such as amino acids and urea. Therefore, the measurement of crude protein in feed occupies a very important position in the detection of feed (Fan, 2014). Based on this, we used the content of crude protein as a screening standard and M-2 as a fermentation strain to explore the optimal fermentation conditions. This means that flaxseed cake fermented by M-2 not only reduced the content of

cyanogenic glycosides, but also increased its crude protein content. Dry matter loss occurs during the fermentation process, but there is no significant change before and after, while the increase in crude protein is significant. This shows that the increase in crude protein content may be due to that nitrogen-fixing bacteria play a major role in the fermentation process.

It has been reported that microbial fermentation of agricultural by-products containing toxic components has been progressing with the application of microorganisms, and the fermentation products can reach the standard of fodder (Vasconcellos et al., 2009). There are also reports that significant effects have been achieved by modern genetic engineering to explain the toxic components of agricultural products or agricultural by-products (Zhu et al., 2010; Wu, 2012). In comparison with the previous research achievements (Feng et al., 2003; Yamashita et al., 2007; Wu et al., 2012), the detoxification effect is even more pronounced, because our fermenting strains came from cattle fed the untreated flaxseed cake for 2 years. Since the microorganisms themselves are derived from the animal body, this ensures the safety of the non-toxic or low-toxicity feed obtained by the fermentation of this strain.

We screened strains with significant detoxification effect and high crude protein yield and explored the fermentation conditions.

### 5. Conclusion

This study isolated 5 β-glucosidase-producing strains from cow dung. The 5 strains were identified: X-1, C. freundii; X-3, P. rettgeri; X-6, P. vulgaris; M-1, G. candidum; and M-2, L. ramosa. Fermentation detoxification results showed that the strain M-2 had the best effect, and the optimum condition was inoculum size 3%, water content 60%, time 144 h, and temperature 32 °C. Under these condition, the removal rate of cyanogenic glucosides reached 89%.

1 According to the K value, the optimum conditions were A_3B_1C_2D_2. According to the R value, the primary and secondary order of single factors that affected the crude protein increment was D > C > A > B.

However, flaxseed cake contains more fat and crude fiber substances in addition to proteinaceous substances. Fat is a beneficial ingredient whereas crude fiber is an anti-nutritional ingredient for animal body. Whether or not the fat component is metabolized during the fermentation of the flaxseed cake with the microorganism, and how to use the microorganisms to degrade the crude fiber therein has become a problem to be considered. In addition, based on the high safety requirements of the feed industry, animal models are still used to evaluate safety before large-scale fermentation is explored using the methods utilized in this study.

**Fig. 7.** Influence of fermentation parameters on crude protein increment by strain M-2. (A) influence of cultivation temperature, (B) influence of cultivation time (C) influence of initial substrate water content, (D) influence of initial inoculum concentration. Results are the average of 3 replicates, and the bars indicate the standard error of 3 replicates.
