Abstract

Background: It has been reported that peroxisome proliferator-activated receptor (PPAR)-γ and their synthetic ligands have direct effects on pancreatic β-cells. We investigated whether PPAR-γ activation stimulates insulin secretion through the up-regulation of GPR40 in pancreatic β-cells.

Methods: Rat insulinoma INS-1 cells and primary rat islets were treated with rosiglitazone (RGZ) and/or adenoviral PPAR-γ overexpression. OLETF rats were treated with RGZ.

Results: PPAR-γ activation with RGZ and/or adenoviral PPAR-γ overexpression increased free fatty acid (FFA) receptor GPR40 expression, and increased insulin secretion and intracellular calcium mobilization, and was blocked by the PLC inhibitors, GPR40 RNA interference, and GLUT2 RNA interference. As a downstream signaling pathway of intracellular calcium mobilization, the phosphorylated levels of CaMKII and CREB, and the downstream IRS-2 and phospho-Akt were significantly increased. Despite of insulin receptor RNA interference, the levels of IRS-2 and phospho-Akt was still maintained with PPAR-γ activation. In addition, the β-cell specific gene expression, including Pdx-1 and FoxA2, increased in a GPR40- and GLUT2-dependent manner. The levels of GPR40, phosphorylated CaMKII and CREB, and β-cell specific genes induced by RGZ were blocked by GW9662, a PPAR-γ antagonist. Finally, PPAR-γ activation up-regulated β-cell gene expressions through FoxO1 nuclear exclusion, independent of the insulin signaling pathway. Based on immunohistochemical staining, the GLUT2, IRS-2, Pdx-1, and GPR40 were more strongly expressed in islets from RGZ-treated OLETF rats compared to control islets.

Conclusion: These observations suggest that PPAR-γ activation with RGZ and/or adenoviral overexpression increased intracellular calcium mobilization, insulin secretion, and β-cell gene expression through GPR40 and GLUT2 gene up-regulation.

Introduction

Peroxisome proliferator-activated receptor (PPAR)-γ is a member of the nuclear receptor family that plays a crucial role in lipid and glucose homeostasis. It is well known that thiazolidinediones (TZDs), synthetic ligands for PPAR-γ, exert their glucose-lowering effects principally via improving peripheral insulin sensitivity [1,2]. However, some studies indicate that TZDs have direct effects on glucose-stimulated insulin secretion (GSIS) and pancreatic β-cell gene expression [3–10]. Furthermore, it has been reported that TZDs protect β-cells from the pro-inflammatory cytokines such as interleukin-1β and interferon-γ [11,12], human islet amyloid polypeptide (h-IAPP) [13,14], free fatty acid (FFA) toxicity [15–18], and endoplasmic reticulum (ER) stress [19].

G-protein-coupled transmembrane receptor 40 (GPR 40) is a membrane-bound FFA receptor mainly expressed in the brain and pancreatic β-cells [20–22]. Accumulating evidence indicates that GPR40 mediates the majority of both acute and chronic effects of FFAs on insulin secretion, including the amplification of GSIS [21,23–29], and the receptor has been suggested to be involved in the control of cell proliferation via extracellular signal-related kinase (ERK), phosphoinositide 3-kinase (PI3K), and PKB...
signaling pathways [30]. PPAR-γ is also expressed in enteroendocrine cells, including cells expressing incretin hormones, glucagon like peptide-1 (GLP-1) and glucose-dependent insulino trophic peptide (GIP), and it modulates FFA-stimulated insulin secretion not only from pancreatic β-cells, but also through the regulation of incretin hormones [31].

Recently, it was reported that TZDs may preferentially activate the PPARγ receptor, resulting in Ca2+ mobilization from thapsigargin-sensitive intracellular stores that would induce cell growth, whereas the endogenous PPAR-γ ligand, 15-deoxy-D12,14-prostaglandin J2 (15 d-PGJ2), did not induce any Ca2+ signal and inhibited cell growth in nonmalignant human bronchial epithelial cells [22,32]. Taken together, TZDs increase intracellular Ca2+ from the ER through PPAR-γ receptor activation in a PPAR-γ-independent manner.

In this context, we investigated whether PPAR-γ activation stimulates insulin secretion through the up-regulation of PPAR-γ in INS-1 cells. We also explored the PPAR-γ downstream signaling pathways involved in the role of PPAR-γ activation in pancreatic β-cells.

### Methods

#### Materials

Rosiglitazone (RGZ) was obtained from Alexis (Leusen, Switzerland). The U-73122 and nifedipine were purchased from Calbiochem (Merk, Nottingham, UK). All other reagents were purchased from Sigma-Aldrich (St. Louis, MO) unless noted.

#### Cell culture

Rat insulinoma INS-1 cells were kindly provided by Dr. P. Maechler (Geneva, Switzerland) [33]. INS-1 cells were maintained in RPMI 1640 medium containing 11 mM glucose supplemented with 10 mM HEPES, 10% heat-inactivated fetal bovine serum (FBS), 2 mM L-glutamine, 1 mM sodium pyruvate, 50 μM β-mercaptoethanol, 100 IU/ml penicillin, and 100 μg/ml of streptomycin in a humidified atmosphere (5% CO2, 95% air). In the starvation condition, RPMI-1640 media containing 2% bovine serum albumin (BSA) was used.

#### Islet isolation

Islets were isolated from the pancreas of male Sprague Dawley rats (Orientbio, Seongnam, Gyeonggi-do, Korea) by distending the pancreatic duct with a mixture of collagenase (Roche). After the digestion at 37°C, the islets were separated on a discontinuous histopaque density gradient (Histopaque 1077; Sigma) and further purified by handpicking. Handpicked islets were cultured in sponge (Spongostan®, Johnson & Johnson, Denmark) with RPMI 1640 medium. All the procedures were approved by the Institutional Animal Care and Use Committee at Samsung Biomedical Research Institute.

#### Ca2+ detection assay

After treatment with RGZ and/or other chemicals for 24 h, cells were stimulated with 16.7 mM glucose in Krebs–Ringer bicarbonate buffer (KRBB) solution for 1 h. After glucose stimulation, cells were treated with 2 μM Fluo-4 (Molecular Probes, Eugene, OR) in calcium and glucose-free KRBB solution for 30 min in the incubator with light protection, and then washed three times with calcium and glucose-free KRBB solution. Cells were observed under a fluorescence microscope (Olympus, Tokyo, Japan).

### Measurement of insulin release

The medium was replaced with defined serum-free medium containing RGZ, and other inhibitors at the designated concentrations. After 24 h of treatment, cells were washed with Krebs-Ringer-bicarbonate-HEPES (KRBB) buffer and incubated for an additional 60 min in 1 ml of KRBB buffer containing 5.6 or 16.7 mM of glucose. Insulin secretion was normalized for cell number by measuring total protein in each experiment with the Bradford assay, and was determined using a rat insulin ELISA kit (Merkodia, Uppsala, Sweden). FFAs including linoleic, oleic and palmitic acid in 0.01 M NaOH was incubated at 60°C for 30 min, and then FFAs were complexed with 5% FFA-free BSA in PBS. The FFA/BSA conjugates were used to treat INS-1 cells.

#### Perfusion for insulin secretion

After PPARγ RNAi transfection, secreted insulin was measured in a perfusion system (Cellnex biosciences, inc., Minneapolis, MN). 1×10⁵ INS-1 cells were cultured in small chambers on Millicell culture inserts. INS-1 cells were perfused in 3.3 mM glucose KRBB media for 30 mins at flow rate of 1 ml/min at 37°C chamber. Glucose concentrations were modified at 16.7 mM concentration. Fractions were collected at 1 min intervals during the 1st peak insulin secretion and then collected at 2 min intervals. Collected fractions were stored at −20°C before performing insulin ELISA.

#### Western blotting

Thirty micrograms of proteins per lane were electrophoresed on 10% polyacrylamide gels and electroblotted onto nitrocellulose membranes (Millipore, Bedford, MA). Blots were blocked with 5% skim milk in Tris-buffered saline containing 0.1% Tween-20 (TTBS) for 40 min and incubated overnight at 4°C with the primary antibodies. Nuclear and cytoplasmic extraction to determine FoxO1 cellular localization was made using NE-PER nuclear and cytoplasmic extraction reagents (Pierce, Rockford, IL) according to the manufacturer instructions. Blots were developed by enhanced chemiluminescence using a standard kit (Amersham Pharmacia Biotech, Piscataway, NJ). Western blot band density was analyzed using a GS-800 calibrated densitometer (Bio-Rad, Hercules, CA, USA).

#### Adenovirus infection & RNAi transfection

Adenovirus containing human PPAR-γ1 complementary DNA was provided by Dr. KS Park (Seoul, Korea) and adenovirus containing rat FoxO1 shRNA was provided by Dr. SH Koo (Seoul, Korea). Adenoviruses were applied to INS-1 cells and islets at 3.0×10⁶ pfu/ml for PPAR-γ overexpression and 1.0×10⁶ pfu/ml for FoxO1 suppression. The efficacy of infection for varying viral loads was determined by LacZ staining for Ad-PPAR-γ and green fluorescent protein (GFP) observation for Ad-FoxO1-GFP (Figure S1A). Insulin receptor, GLUT2, and PPAR-γ40 sequence-specific silencing was performed with 100 pM/μl of RNAi (Bioneer, Daejeon, Korea) using HiPerFect transfection reagent (Invitrogen, San Francisco, CA), according to the manufacturer’s instructions. Suppression of target proteins was measured with Western blots (Fig. S1B).

#### Hoechst 33258 staining

Hoechst-33258 (bisbenzimide trihydrochloride, HO258; Calbiochem, La Jolla, CA) was used to detect cell apoptosis. Nuclei were visualized under a fluorescence microscope (Olympus, Tokyo, Japan) at 348 nm (excitation) and 490 nm (emission).
Oral glucose tolerance test (OGTT)

All procedures were performed in accordance with the recommendations in the Guide for the Care and Use of Laboratory Animals of the National Institutes of Health. The protocol was approved by the Committee on the Ethics of Animal Experiments of the Samsung Biomedical Research Institute (SBRI), Sungkyunkwan University School of Medicine (Permit Number: H-B0-043). Male OLETF rats and their diabetes-resistant counterparts, LETO rats, were supplied by Tokushima Research Institute (Otsuka Pharmaceutical, Tokushima, Japan) at 8 weeks of age. At an age of 10 weeks, OLETF rats were randomly assigned to the RGZ treatment or control group, and 3 mg/kg of RGZ was given by mouth through gavage. After 14 weeks of RGZ treatment (24 weeks of age), OGTT was performed. Glucose (2 g/kg) solution was given orally, and serum glucose levels were measured before (0 min) and 30, 60, 90 and 120 min after glucose loading.

Hyperinsulinemic euglycemic clamp

One week before the experiment, animals were chronically cannulated in the jugular vein for infusion of glucose and insulin, and in the carotid artery for sampling. Cannulae were tunneled subcutaneously and exteriorized at the back of the neck. Animals were allowed 7 days to recover from surgery and to regain body weight. RGZ-treated rats continued to receive a RGZ-containing chow during the recovery period. Food was withdrawn 6 h before the hyperinsulinemic-euglycemic clamping. After 14 weeks of treatment (24 weeks of age), hyperinsulinemic-euglycemic clamp studies were performed. Basal samples were drawn at −30 and 0 min. Animals were exposed to a hyperinsulinemic clamp in which the insulin infusion rates were 4 (sub-maximum) and 40 (maximum) mU/kg/min. Blood was sampled for measurement of plasma glucose concentration every 5 min and for insulin levels every 20–30 min. Plasma glucose concentrations were immediately determined, and the remaining sample was stored at −20°C for later assay.

Immunohistochemistry

At 24 weeks of age, OLETF rats were sacrificed by an intraperitoneal injection of sodium pentobarbital (45 mg/kg), and all efforts were made to minimize suffering. Specimens were obtained from the distal end of the pancreas. The tissue was fixed in 4% paraformaldehyde, dehydrated, embedded in paraffin, and sequentially sectioned.

Statistics

The data are presented as the means ± SD. The Mann-Whitney tests were performed to compare differences between two independent groups. One-way ANOVA with post-hoc analyses were used to compare differences between several groups. P values <0.05 were considered statistically significant (PRISM; Graphpad Software Corp., San Diego, CA).

Results

Effects of PPAR-γ activation on insulin secretion and intracellular calcium mobilization

Figure 1A showed that 24 h of treatment with 10 μM RGZ increases GSIS in high (16.7 mM) glucose conditions (P<0.01 vs.
control, and adenoviral PPAR-γ overexpression also exhibits increased insulin secretion on stimulation with 16.7 mM glucose. Furthermore, co-treatment with RGZ and PPAR-γ overexpression augmented the insulin secretion compared with PPAR-γ overexpression alone. However, 10 μM RGZ treatment did not show any increment in insulin secretion in basal (5.6 mM) glucose conditions (Fig. 1A, B). The stimulatory activities of 10 μM oleic or linoleic acids for 30 minutes on insulin secretion were detected more strongly when pretreated with 10 μM RGZ, indicating that FFAs amplify RGZ-stimulated insulin secretion from INS-1 cells (Fig. 1C). In accordance with the results of insulin secretion, Fluo-4 stained intracellular calcium was increased with RGZ treatment or PPAR-γ overexpression compared with control, and co-treatment with RGZ and PPAR-γ overexpression showed a synergetic effect on intracellular calcium mobilization (Fig. 1D).

RGZ induces intracellular calcium mobilization from extra- and intra-cellular sources

To determine the sources of increased intracellular calcium in response to PPAR-γ activation, we used 10 mM nifedipine to block the calcium influx from the extracellular source. Compared with RGZ treatment alone, co-treatment with RGZ and nifedipine decreased the Fluo-4 stained calcium (Fig. 2A). As is the case of nifedipine, 0.1 μM thapsigargin treatment blocked the RGZ-induced intracellular calcium mobilization (Fig. 2A). Taken together, PPAR-γ activation increases intracellular calcium from both extra- and intra-cellular sources and as expected, RGZ-induced insulin secretion was decreased with nifedipine and thapsigargin treatment under high glucose conditions (Fig. 2B).

Figure 2. RGZ induces intracellular calcium mobilization from extra- and intra-cellular sources. (A) Effects of nifedipine (10 mM), thapsigargin (0.1 μM), and GLUT2 sequence-specific silencing with RNAi on 10 μM RGZ-induced intracellular calcium mobilization and (B) insulin secretion (ANOVA within same glucose conditions: n = 4, *P<0.01 vs. RGZ treatment with 5.6 mM glucose; **P<0.05 vs. non-treatment with 16.7 mM glucose; and ***P<0.01 vs. RGZ treatment with 16.7 mM glucose) (C) Immunoblot for GLUT2 expression with 10 μM RGZ treatment and/or adenoviral PPAR-γ overexpression.

doi:10.1371/journal.pone.0050128.g002

PPAR-γ activation increases intracellular calcium concentration and insulin secretion through GPR40 gene up-regulation

We first investigated whether or not PPAR-γ activation up-regulated GPR40 expression in INS-1 cells. As shown in Figure 3A, 24 h treatment with RGZ and/or adenoviral PPAR-γ overexpression increased GPR40 expression. In contrast, the level of expression of cyclic-AMP-responsive exchange factor, Epac2, a cAMP sensor for Ca²⁺ mobilization, showed no changes with RGZ and/or PPAR-γ overexpression (Fig. 3A). However, the expression of GPR40 was not changed with 1, 4, and 12 h of treatment with RGZ (Fig. S2A). We next studied whether or not PPAR-γ activation increases calcium mobilization through the
GPR40-mediated PLC signaling pathway. As expected, RGZ-mediated intracellular calcium mobilization was significantly reduced with the PLC inhibitor, U-73122, compared to RGZ alone (Fig. 3B), and insulin secretions were significantly decreased with the PLC inhibitors compared to RGZ treatment alone (Fig. 3C).

To further examine the role of GPR40 for RGZ-mediated insulin secretion, we reduced GPR40 expression in INS-1 cells with RNA interference (RNAi) specific for rat GPR40. INS-1 cells expressing RNAi against GPR40 showed nearly 100% reduction in the protein level compared to cells containing control vector, as analyzed by Western blot (Fig. 3B). The RGZ-induced increase in the Ca$$^{2+}$$ signal was completely abolished in cells transfected with GPR40-specific RNAi. Likewise, insulin secretion was significantly decreased with GPR40 RNAi. Interestingly, U-73122 treatment showed additional inhibitory effects on insulin secretion and intracellular calcium mobilization compared to GPR40 RNAi transfection alone (Fig. 3D, E). Taken together, these results suggest that RGZ increases intracellular calcium mobilization and insulin secretion through the GPR40-mediated PLC signaling pathway in INS-1 cells. In addition, co-treatment with RGZ and PPAR-$$\gamma$$ overexpression increased intracellular calcium mobilization and insulin secretion, and was completely blocked by the treatment with GLUT2 RNAi or GPR40 RNAi (Fig. 3F, G).

In perfusion experiments, exposure of the INS-1 cells to 16.7 mM glucose resulted in a rapid increase in 1$$^{st}$$ and 2$$^{nd}$$ phase insulin release above basal level. In addition, the addition of 10 $$\mu$$M RGZ potentiated 2.5- and 1.3-fold in 1$$^{st}$$ and 2$$^{nd}$$ phase insulin release compared to 16.7 mM glucose alone ($$P$$<0.05). However, GPR40 RNAi caused a nearly complete inhibition of the insulin release evoked by 10 $$\mu$$M RGZ (Fig. 3H).

PPAR-$$\gamma$$ activation induces the CaMKII and CREB signaling pathways through GPR40 and GLUT2 gene up-regulation.

Next, we examined the downstream signaling pathway of intracellular calcium mobilization. After treatment with RGZ and/or PPAR-$$\gamma$$ overexpression, the phosphorylated levels of CaMKII and downstream CREB were significantly increased, and induced an increase in the levels of IRS-2 and phosphorylated Akt. However, no changes were observed in the level of insulin receptor expression with treatment of RGZ and/or PPAR-$$\gamma$$ overexpression (Fig. 4A). As shown above, RGZ and/or PPAR-$$\gamma$$ overexpression increased insulin secretion, and thus we examined whether increased levels of IRS-2 and phosphorylated Akt was due to an increased insulin autocrine effect or directly due to the up-regulation of the CaMKII and CREB signaling pathways. After insulin receptor-specific RNAi, expression of insulin receptor was completely blocked, and no increases were noted with RGZ and/or PPAR-$$\gamma$$ overexpression in insulin receptor expression. However, the levels of IRS-2 and phosphorylated Akt was increased in the absence of insulin receptor expression with the treatment of RGZ and/or PPAR-$$\gamma$$ overexpression (Fig. 4A). Therefore, the increased levels of IRS-2 and phosphorylated Akt by PPAR-$$\gamma$$ activation were not by augmented insulin signaling, but by a direct mechanism mediated by up-regulated CaMKII and CREB signaling pathways. In addition, the phosphorylated level of Akt after 10 $$\mu$$M insulin treatment was increased with RGZ and/or PPAR-$$\gamma$$ overexpression compared with the non-treated control (Fig. 4A).

We further examined the roles of PPAR-$$\gamma$$ activation on $$\beta$$-cell specific gene expression and whether or not it was mediated by GPR40 and GLUT2 up-regulation. After treatment with RGZ and/or PPAR-$$\gamma$$ overexpression, the level of expression of the $$\beta$$-cell specific genes, including Pdx-1 and FoxA2, were increased (Fig. 4B), and the GPR40 RNAi or GLUT2 RNAi reduced the levels of phospho-CaMKII, phospho-CREB, IRS-2, phospho-Akt, Pdx-1, and FoxA2 which was mediated by treatment of RGZ and/or PPAR-$$\gamma$$ overexpression (Fig. 4C). In addition, the level of expression of BETA2/NeuroD was increased with the treatment of RGZ or adenoviral PPAR-$$\gamma$$ overexpression. However, no changes were observed in MafA expression with PPAR-$$\gamma$$ activation (data not shown).

To determine whether RGZ treatment up-regulates GPR40 expression in a receptor-dependent manner, we treated 50 $$\mu$$M GW9662 together with RGZ. As a result, the levels of GPR40, phospho-CaMKII, phospho-CREB, IRS-2, phospho-Akt, Pdx-1, and FoxA2 were reduced, and therefore it may be that RGZ treatment increased CaMKII and CREB signaling pathways through GPR40 up-regulation in a receptor-dependent manner (Fig. 4D).

PPAR-$$\gamma$$ activation up-regulates $$\beta$$-cell gene expression through FoxO1 nuclear exclusion.

We examined whether PPAR-$$\gamma$$ activation affects the nuclear-cytoplasm shuttling of FoxO1. Under basal condition (serum-free 16.7 mM glucose in RPMI-1640 media), FoxO1 was exclusively located in the nucleus; however, PPAR-$$\gamma$$ activation with RGZ and/or PPAR-$$\gamma$$ overexpression translocated FoxO1 from nucleus to cytoplasm in INS-1 cells (Fig. 5A). In agreement with immunofluorescence staining results, FoxO1 was translocated from the nucleus to the cytoplasm, and exclusively located in the cytoplasm with RGZ and/or PPAR-$$\gamma$$ overexpression in Western blotting (Fig. 5B).

Next, we examined whether or not PPAR-$$\gamma$$-mediated FoxO1 nuclear exclusion is dependent on PPAR-$$\gamma$$-mediated insulin secretion. Even though the expression of insulin receptor was completely blocked with insulin receptor RNAi, FoxO1 was translocated to the cytoplasm with RGZ treatment (Fig. 5C). In addition, the expression of $$\beta$$-cell genes, including FoxA2 and Pdx-1, was up-regulated with RGZ treatment, despite the insulin receptor RNAi, and combined treatment with RGZ and FoxO1 RNAi showed a synergetic effect on $$\beta$$-cell gene expression.
compared to either RGZ treatment or FoxO1 RNAi alone (Fig. 5C, D).

RGZ treatment prevents lipotoxic and ER stress-induced β-cell apoptosis
To determine the role of RGZ on β-cell death, we treated INS-1 cells with 1.0 mM palmitate or 50 μM thapsigargin for 24 h and assessed β-cell apoptosis with Hoechst 33258 staining. The number of fluorescence-stained cells increased with lipotoxic or ER stress conditions compared with control cells; however, the addition of RGZ with palmitate or thapsigargin treatment reduced β-cell apoptosis (Fig. 6A, B). In support of β-cell apoptosis prevention, RGZ treatment reduced the level of expression of CHOP induced by thapsigargin treatment. In addition, RGZ treatment reduced the levels of expression of ER stress markers including p-PERK, p-eIF2α, and CHOP induced by 1.0 mM palmitate (Fig. 6C, D).

PPAR-γ activation increases GPR40 expression in primary rat islets and OLETF rats
In agreement with the results of INS-1 cells, 24 h treatment with 10 μM RGZ and/or adenoviral PPAR-γ overexpression increased GPR40 expression in primary islets. In addition, PPAR-γ activation with RGZ and/or adenoviral PPAR-γ overexpression increased GSIS in high (16.7 mM) glucose conditions. However, GSIS did not increase in RGZ treatment in the case of basal (5.6 mM) glucose conditions (Fig. 7A, B). We next performed metabolic tests including OGTT and euglycemic clamping. RGZ treated OLEFT rats showed significantly reduced blood glucose levels compared with non-treated OLEFT rats (Fig. 7C). To assess the insulin sensitivity in OLETF rats, hyperinsulinemic-euglycemic clamp studies were performed. Maximal glucose infusion rate (GIR) was significantly higher in RGZ-treated OLEFT rats (n = 4) compared with untreated OLEFT rats (n = 4) at 24 weeks (7.91±2.32 mg/kg/min in OLEFT rats and 16.10±4.39 mg/kg/min in RGZ-treated OLEFT rats, P<0.05). However, there was no significant difference between treated and untreated OLEFT rats with submaximal GIR (Fig. 7D). In immunohistochemical staining, RGZ-treated islets were relatively well-preserved, and there was stronger positive insulin staining. In addition, GLUT2, IRS-2, Pdx-1, and GPR40 were more strongly expressed in RGZ-treated islets compared to control islets (Fig. 7E).

Discussion
There is mounting evidence that TZDs protect pancreatic β-cells from a variety of noxious stimuli, including excessive nutrients, cytokines, h-IAPP, and ER stress [11–19], and a recent human study also concurs with the protective role of TZD on β-cell function compared to other anti-diabetic drugs, such as
sulfonylurea and metformin [34]. However, it is still obscure as to the precise mechanisms of PPAR-γ activation that regulate β-cell function and mass, and although there are many studies that TZDs protect β-cells from lipoapoptosis in diabetic rats [17], it is still elusive whether the protective role of TZDs is direct or secondary to lowered blood glucose from improved insulin sensitivity. Moreover, there is significant controversy about whether or not PPAR-γ activation increases GSIS in pancreatic β-cells. Some of the previous studies have shown that PPAR-γ activation with TZDs and/or PPAR-γ overexpression is detrimental to β-cell function, and suppresses insulin secretion and proinsulin biosynthesis [7,35–38]. For example, it has been reported that troglitazone activates AMP-activated protein kinase and inhibits insulin secretion from MIN6 cells [37], and PPAR-γ overexpression suppresses insulin secretion in isolated pancreatic islets through induction of UCP-2 protein [35]. Moreover, Schinner et al. [39] reported that human insulin gene promoter activity is inhibited by RGZ and PPAR-γ. However, other studies have demonstrated the contradictory results of TZDs or PPAR-γ, which showed the PPAR-γ-stimulated insulin secretion in pancreatic β-cells [3,8–10]. In terms of β-cell gene expression, Moibi et al. [6] showed that Pdx-1, Nkx6.1, glucokinase and GLUT2 were increased after treatment with troglitazone for 3 days in INS-1 cells, and knockdown of PPAR-γ with RNAi lowered the mRNA levels of Pdx-1, glucokinase, GLUT2, and proinsulin II by more than half. Moreover, it was reported that some of the key β-cell genes, including Pdx-1, GLUT2, and glucokinase, have PPARE in the promoter region [4,5,40].

In the current study, we showed that RGZ and/or adenoviral PPAR-γ overexpression increase insulin secretion in high glucose conditions, and intracellular calcium mobilization is important in this step. Therefore, treatment with nifedipine and thapsigargin that blocked the extracellular and intracellular calcium sources, respectively, decreased RGZ-induced insulin secretion. Apart from insulin secretion, RGZ and/or PPAR-γ overexpression increase β-cell gene expression including Pdx-1, FoxA2, and BETA2/NeuroD. Similar to our results, Richardson et al. [41] showed that >24 h treatment with RGZ promoted the nuclear accumulation of IPF1 and FoxA2 independent of glucose concentration, and stimulated a two-fold increase in the activity of the Ipf1 gene promoter. Several explanations are possible regarding the mechanism of PPAR-γ-induced β-cell gene expression. First, putative PPARE was identified in the mouse Pdx-1 promoter, and TZDs increase Pdx-1 expression through a PPAR-γ-mediated mechanism [4]. Second, it may be possible that the increased Pdx-1 and FoxA2 expression is due to FoxO1 nuclear exclusion by PPAR-γ activation. Because FoxO1 and FoxA2 share common DNA binding sites in the Pdx-1 promoter, they compete with each other for binding to the Pdx-1 promoter [42]. Therefore, RGZ-induced FoxO1 nuclear exclusion leads to increase FoxA2 binding to the Pdx-1 promoter, resulting up-regulation of Pdx-1 gene expression. To exclude the possibility that RGZ treatment induces
FoxO1 nuclear exclusion merely through the increased insulin secretion, we blocked the insulin signalling pathway via insulin receptor RNAi, and assessed FoxO1 cellular localization. Although, the expression of insulin receptor was completely blocked, FoxO1 was translocated from the nucleus to the cytoplasm with the RGZ treatment, and thus it seems that there may be a direct mechanism in PPAR-γ-induced FoxO1 nuclear exclusion rather than PI3K–Akt pathway mediated FoxO1 shuttling. In agreement with our findings, Dowell et al. [43] reported that FoxO1 was identified as a PPAR-γ-interacting protein in a yeast two-hybrid screen, and PPAR-γ and RXRA expression vector and/or RGZ treatment resulted in a dose-dependent inhibition of Foxo1-driven reporter activity. Interestingly, PPAR-γ-induced increased calcium mobilization and insulin secretion is mediated by FFA receptor GPR40 gene induction, and was completely blocked by the PLC inhibitor, U-73122, or direct GPR40 RNAi. This is the first evidence showing the novel mechanism of PPAR-γ that increases insulin secretion in pancreatic β-cells. In addition, the expression of Pdx-1 and FoxA2 following RGZ treatment and/or PPAR-γ overexpression was up-regulated in a GPR40-dependent manner. In agreement with our findings, it has been reported that the HR region in the 5’-flanking region of the GPR40 gene showed a strong β-cell-specific enhancer activity, and can bind the Pdx-1 and BETA2 both in vitro and in vivo [44].

Recently, Gras et al. [32] reported that TZDs bind to the GPR40 receptor, resulting in Ca²⁺ mobilization from ER calcium stores, and which induce the proliferation of non-malignant human bronchial epithelial cells. However, the non-TZD PPAR-γ ligand, 15 d-PGJ₂, did not induce any Ca²⁺ signal and instead inhibited cell growth. Collectively, this study suggested that TZDs increase intracellular calcium through the GPR40 activation in a

Figure 6. RGZ treatment prevents lipotoxic and ER stress-induced β-cell apoptosis. (A, B) INS-1 cells were pretreated with or without RGZ (10 μM) and challenged with palmitate (1.0 mM) or thapsigargin (50 μM) for 24 h. Cell apoptosis was examined by Hoechst staining. receptor-independent manner. The receptor-independent effects of TZDs include anti-inflammatory actions, anti-proliferative effects and cell apoptosis, inhibition of mitochondrial function, and modification of energy metabolism, and based on several findings include the following: (1) the concentrations needed to demonstrate TZD actions were much greater than the reported

Figure 7. PPAR-γ activation increases GPR40 expression in primary rat islets and OLETF rats. (A) Primary rat islets were treated with 10 μM RGZ for 24 h, and incubated for an additional 1 h in 5.6 or 16.7 mM of glucose. Insulin was determined using a rat insulin ELISA kit (ANOVA within same glucose conditions; n = 4, *P < 0.05 vs. control with 5.6 mM glucose; **P < 0.01 vs. RGZ or adenoviral PPAR-γ overexpression with 5.6 mM glucose; †P < 0.01 vs. control with 16.7 mM glucose; and ††P < 0.01 vs. RGZ with 16.7 mM glucose). (B) Immunoblot for GPR40 expression with 10 μM RGZ treatment and/or adenoviral PPAR-γ overexpression. (C) At 10 weeks of age, OLETF rats were randomly assigned to the RGZ treatment or control group, and 3 mg/kg of RGZ was given by mouth through gavage. After 14 weeks of RGZ treatment (24 weeks of age), oral glucose tolerance test was performed (n = 4, *P < 0.05 vs. OLETF rats). (D) At 24 weeks of age, hyperinsulinemic euglycemic clamping was performed and glucose infusion rate was measured (ANOVA within same groups: n = 4, *P < 0.05 vs. OLETF rats or OLETF rats + RGZ; †P < 0.05 vs. OLETF rats). (E) Immunohistochemical staining of GLUT2, IRS-2, Pdx-1, and GPR40.
doi:10.1371/journal.pone.0050128.g007
CREB, IRS-2, and phospho-Akt were up-regulated by PPAR-γ we knocked down the insulin receptor with RNAi. Even after the up-regulation of the CaMKII and CREB signaling pathway, activation. To determine whether or not the increased IRS-2 and phospho-Akt levels are direct through the up-regulated CaMKII and CREB signaling pathways and these results may partly explain the protective role of RGZ from lipotoxic or ER stress induced β-cell apoptosis in this study.

In contrast to the short-term effect of FFAs on insulin secretion, long-term exposure of islets to FFAs results in impaired GSIS through intracellular accumulation of lipid signaling molecules that inhibit insulin secretion [23]. Therefore, some studies questioned the beneficial role of PPAR-γ in β-cell function. Lan et al. [49] suggested that even though PPAR-γ is required for normal insulin secretion in response to FFAs, Ffar1+/- and Ffar1-/- mice had similar weight, adiposity, hyperinsulinemia, and lipid accumulation in livers on high-fat diets. Moreover, Steneberg et al. [50] showed that PPAR-γ-deficient β-cells secrete less insulin in response to FFAs, and loss of PPAR-γ protects mice from obesity-induced metabolic derangements. Conversely, overexpression of PPAR-γ in β-cells leads to impaired β-cell function, hyperinsulinemia, and diabetes, therefore, the authors suggested that PPAR-γ may play a key role in the development of type 2 diabetes. Furthermore, it was reported that PPAR-γ activation may have the potential to inhibit insulin secretion through the opening of ATP-dependent K+ channels in rat β-cells [51]. At present, we could not explain the reason why the studies showed a different role of PPAR-γ from our results, and therefore further studies are necessary to clarify the role of PPAR-γ on pancreatic β-cell function following stimulation with FFAs and during the development of diabetes.

In conclusion, our results demonstrate that PPAR-γ activation through TZDs and/or adenosinergic overexpression increases intracellular calcium mobilization and insulin secretion in INS-1 cells, and which was mediated by the up-regulation of FFA receptor GPR40 and GLUT2 expression. Moreover, the PPAR-γ-mediated GPR40 activation increased the level of expression of β-cell genes, including Pdx-1 and FoxA2.

Supporting Information

Figure S1 (A) Overexpression of PPAR-γ and suppression of FoxO1 in INS-1 cells. Efficiency of adenovirus was determined by X-gal staining, GFP expression, and Western blotting. (B) Inhibition of GPR40, GLUT2, and IR-β expression with RNAi transfection. As the RNAi concentrations increased, target protein expressions were suppressed with RNAi transfection. (TIF)

Figure S2 (A) Acute effect of rosiglitazone on GPR40 expression in INS-1 cells. (B) Acute effect of rosiglitazone on insulin secretion in INS-1 cells (n = 4, *P<0.01 vs. 0 hr). (TIF)
