Abstract
Abnormally increased beta bursts in cortical-basal ganglia-thalamic circuits are associated with rigidity and bradykinesia in patients with Parkinson’s disease. Increased beta bursts detected in the motor cortex have also been associated with longer reaction times in healthy participants. Here we further hypothesize that suppressing beta bursts through neurofeedback training can improve motor performance in healthy subjects. We conducted a double-blind sham-controlled study on 20 human volunteers (10 females) using a sequential neurofeedback-behaviour task with the neurofeedback reflecting the occurrence of beta bursts over sensorimotor cortex quantified in real-time. The results show that neurofeedback training helps healthy participants learn to volitionally suppress beta bursts in the sensorimotor cortex, with training being accompanied by reduced reaction time in subsequent cued movements. These changes were only significant in the real feedback group but not in the sham group, confirming the effect of neurofeedback training over simple motor imagery. In addition, reaction times correlated with the rate and accumulated duration of beta bursts in the contralateral motor cortex before the Go cue, but not with averaged beta power. The reduced reaction times induced by neurofeedback training positively correlated with reduced beta bursts across all tested hemispheres. These results strengthen the link between the occurrence of beta bursts in the sensorimotor cortex before the Go cue and slowed movement initiation in healthy motor control. The results also highlight the potential benefit of neurofeedback training in facilitating voluntary suppression of beta bursts in order to speed up movement initiation.

Significance
This double-blind sham-controlled study suggested that neurofeedback training can facilitate volitional suppression of beta bursts in sensorimotor cortex in healthy motor control better.
than sham feedback. The training was accompanied by reduced reaction time in subsequent cued movements, and the reduced reaction time positively correlated with the level of reduction in cortical beta bursts before the Go cue, but not with average beta power. These results provide further evidence of a causal link between sensorimotor beta bursts and movement initiation and suggest that neurofeedback training could potentially be used to train participants to speed up movement initiation.

**Keywords:**

Beta oscillations, neurofeedback training, beta burst, movement initiation
Introduction

Beta band oscillations are a prominent feature in the cortical-basal ganglia motor network, and prove to be consistently modulated by movements and motor imagery when averaged over multiple trials (McFarland et al., 2000; Pfurtscheller et al., 2003). More recent studies have emphasized the importance of the temporal dynamics of the beta oscillations and found that transient events of high-amplitude beta oscillations (beta bursts) in the cortical-basal ganglia motor network predict sensorimotor behavior (Feingold et al., 2015; Sherman et al., 2016). In particular, the rate of beta bursts in the sensory cortex occurring close to the stimulus was more likely to impair perception (Shin et al., 2017). The timing of beta bursts in the motor cortex prior to movement was related to the duration of motor preparation, with later bursts resulting in delayed response times (Little et al., 2019). Wessel (2019) also found that an increased rate of beta bursts in the contralateral sensorimotor cortex following a Go cue predicted a longer reaction time. However, all these studies are correlational, and it is still not clear whether modulating sensorimotor beta bursts can lead to changes in motor preparation and movement initiation.

Neurofeedback training has been proposed as a promising technique to train patients to self-regulate pathological brain activities in order to improve symptoms (Daly and Wolpaw, 2008; Erickson-Davis et al., 2012; Ros et al., 2014; Huster et al., 2014; Azarpaikan et al., 2014; Fukuma et al., 2018). It also offers the potential to provide more causal inference about manipulated brain states and their behavioral consequences. Khanna and Carmena (2017) trained healthy macaque monkeys to perform a sequential neurofeedback-motor task paradigm and showed that reaching movements preceded by a reduction in cortical beta power achieved through neurofeedback training exhibited significantly faster movement onset times than those preceded by an increase in beta power. Similarly, healthy human
participants can also learn to voluntarily modulate beta oscillations measured over the sensorimotor cortex with neurofeedback training (Vernon et al., 2003; Boulay et al., 2011; Witte et al., 2013). Combined behavioral tasks showed that increasing amplitude sensorimotor beta rhythms were associated with longer reaction times than decreasing amplitude sensorimotor beta rhythms (Boulay et al., 2011; McFarland et al., 2015). However, there were large variations between participants in terms of the effect of the neurofeedback training (McFarland et al., 2015). In addition, there is a lack of proper sham control in most neurofeedback studies to determine whether veritable neurofeedback was the primary factor accounting for observed behavioral alterations, or whether other mental strategies were mediating the effects (Thibault et al. 2015; 2016). This is particularly relevant for neurofeedback studies targeting sensorimotor beta oscillations since beta activity can be reduced by motor imagery and attention (Pfurtscheller et al., 2001; Vukelić et al., 2019). A clear association between neurofeedback training and enhanced performance both in terms of self-regulation of EEG beta bursts and motor skills has yet to be established (Jeunet et al., 2019).

In this study, we conducted a double-blind sham-controlled study in healthy young participants using a sequential neurofeedback-behaviour task with the visual feedback specifically indicating the occurrence of high amplitude beta bursts measured from motor cortex. The results show that veritable neurofeedback training helped participants learn to suppress cortical beta bursts better than sham feedback. The ‘Real Feedback’, but not ‘Sham Feedback’, training was accompanied by reduced reaction time in subsequently cued movements. Moreover, the reaction time of the motor task significantly correlated with the beta burst characteristics (burst rate and accumulated duration) before the Go cue across all tested hemispheres, but not with the averaged beta power. The changes in the accumulated...
beta bursts before Go-Cue induced by the neurofeedback training correlated with the changes in subsequent reaction time. These results strengthen the link between cortical beta bursts and movement initiation and further suggest that neurofeedback training could be a potential tool to train participants to speed up movement initiation in healthy participants and in patients with movement disorders such as Parkinson’s disease.

Methods and Materials

Ethics
The present study was conducted in accordance with the Declaration of Helsinki, approved by local ethics committee and all participants provided informed written consents before the experiments.

Participants
Twenty young healthy participants aged 18-21 (10 female) were recruited for this study. The participants were pseudo-randomly assigned to a ‘Sham Feedback’ group or a ‘Real Feedback’ group, with ten participants in each group. The existence of a ‘Sham Feedback’ group was blinded to all participants. Both the participants and the experimenter who gave instructions and conducted the recordings were blinded about the group each participant was assigned to, resulting in a double-blind sham-controlled design.

Experimental protocol
The neurofeedback training paradigm was similar to that presented in our previous study (He et al., 2019). As shown in Fig. 1, the training composed of multiple short trials. Each trial consisted of a 2-s period where the participants were instructed to get ready and a 4-s neurofeedback phase, which was followed by black screen presented for a time randomly...
drawn between 2 and 3 seconds and then a movement Go cue. The participants were instructed to perform a thumb of finger pinch movement as fast as possible in response to the Go cue to generate a force overshooting a predefined force level (50% of the maximum voluntary force measured before starting the task). Feedback about the reaction time of the pinch movement was provided to the participants at the end of the trial in order to keep participants engaged and to encourage them to be as fast as possible throughout the experiment.

During the neurofeedback phase, a basketball appeared in the top-left corner of a computer screen at the beginning of each trial (Fig. 1A). The position of the basketball was updated every 250 ms. The horizontal displacement for each update was constant so that the basketball moved toward the right of the screen at a constant speed during the trial. In the ‘Real Feedback’ group, the vertical movement of the basketball was driven by the real-time detection of beta bursts (when the average beta power over the previous 500 ms window was over a predefined threshold) based on the EEG signal recorded from the sensorimotor cortex ("C3" or "C4"). If a beta burst was detected, the ball would drop by a fixed distance. Therefore, for the ‘Real’ feedback group, the final vertical position of the basketball at the end of each trial indicated how often beta bursts were detected. For the ‘Sham Feedback’ group, the vertical position of the ball determined in the same way but was driven by the beta power calculated based on a replay of resting EEGs recorded from six healthy controls (aged 25-35, 3 females, 10 min resting for each of them) who did not participate in the main study. Specifically, at the beginning of each experiment for the ‘Sham Feedback’ group, we randomly selected a resting EEG dataset previously recorded and randomly selected a start point within the first 5 s for the replay. Each participant completed four ‘Training’ blocks and four ‘No Training’ blocks on each recording day, with 10 trials in each block. The instruction
for each block was presented for 10 s before the block starts (Fig. 1B). Instructions given to
the participants were the same for both groups. In the ‘Training’ trials, the participants were
instructed to keep the basketball floating at the top of the screen by preventing it from
dropping. Participants were informed that motor imagery might help with the task, but they
were also encouraged to try different strategies. In the ‘No Training’ trials, the participants
were instructed to simply pay attention to the movement of the ball displayed on the screen
and get ready for the subsequent movement Go cue. This design allowed us to look at the
within-subjects effect of the neurofeedback ‘Training’ vs ‘No Training’ conditions and the
between-subjects effect of the ‘Real Feedback’ vs ‘Sham Feedback’ groups. In order to
reduce frustration for participants in the ‘Sham Feedback’ group, we manually increased the
threshold that triggered the drop of the basketball in the ‘Training’ condition by 20% so that
the basketball was less likely to drop in the ‘Training’ condition. This manipulation was to
give the participants the feeling of controlling the basketball and to reduce frustration.

Each participant was recorded for three times over three different days, with an average of
2.175 ± 0.27 days (mean ± SEM) between each recording day. On each recording day, the
participant performed the neurofeedback training task with each hemisphere using the EEG
signals recorded around the left/right sensorimotor cortex area, i.e., “C3” or “C4” (in a
random order), and the contralateral hand for the motor task. Participants completed four
experimental runs for each hemisphere on each training day. Each experimental run consisted
of a 30 second of rest recording in order to calibrate the threshold for triggering the vertical
movement of the basketball (see the Calibration section below), 10 continuous trials in the
‘Training’ condition, and another 10 continuous trials in the ‘No Training’ condition. The
order of ‘Training’ and ‘No Training’ blocks in each experimental run was randomized. In
total, we recorded data from 20 hemispheres with 120 trials in each of the ‘Training’ and ‘No
Training’ conditions for each hemisphere for each of the ‘Real Feedback’ and ‘Sham Feedback’ groups.

Calibration
Two calibrations were performed for each tested hemisphere in order to: 1) select the hemisphere-specific beta frequency band for the online experiment, and 2) determine the threshold $T$ above which real-time quantified beta power would trigger the vertical movement of the basketball in each experimental run.

First, each participant performed 30 trials of cued finger pinch movements with each hand before the experiments on the first training day. Data recorded during this task were processed offline using a continuous wavelet transform. The peak frequency ($f_p$) in the beta band (13-30 Hz) with maximal movement-related power reduction in the EEG channel located in the motor cortex (“C3” or “C4”) contralateral to the hand performing the pinch movements was identified. Then a 5 Hz frequency-band centered around $f_p$ ($[f_p - 2, f_p + 2]$ Hz) was used as the hemisphere-specific beta frequency-band. In the current study, the peak frequencies selected for the “Real Feedback” and “Sham Feedback” groups were 19.10 ± 0.52 Hz (mean ± SEM, range between 15 Hz and 24 Hz) and 19.20 ± 0.57 Hz (range between 15 Hz and 24 Hz), respectively. Second, at the beginning of each experimental run, during a 30 s rest period, the average beta power over each 500 ms window was estimated in real-time with a 250 ms update interval, resulting in 118 beta power values. Then the 75th percentile of these values was set as the threshold $T$ for the current experimental run.

Recordings
Twenty-four EEG channels covering “FP1”, “FP2”, “Fz”, “FCz”, “FC1”, “FC2”, “FC3”, “FC4”, “C3”, “C4”, “P3”, “P4”, “O1”, “O2”, “F7”, “F8”, “T7”, “T8”, “F3”, “F4”, “T3”, “T4”, “T5”, “T6”, “P7”, “P8”, “O1”, “O2”. 
“Cz”, “C1”, “C2”, “C3”, “C4”, “CPz”, “CP1”, “CP2”, “CP3”, “CP4”, “P3”, “Pz”, “P4”, “Oz”, “O1”, and “O2” according to the standard 10-20 system were recorded using a TMSi Porti amplifier (TMS International, Netherlands) at a sampling rate of 2048 Hz with a common average reference. Electromyography (EMG) signals from the flexor carpi radialis of both arms and measurements from 3-dimensional accelerometers attached to the back of both hands were simultaneously recorded to monitor if the participants made any actual movements during the neurofeedback training. The generated force in the cued pinch movements was recorded using a pinch meter (Biometrics Ltd). The real-time positions (X, Y) of the basketball in each trial and the timing of the Go cue were also recorded and synchronised with all electrophysiological recordings through an open-source software toolkit (Lab Streaming Layer; LSL). The paradigm used in this study was developed in C++ (Visual Studio 2017, Microsoft) and the online/offline data processing was achieved in Matlab (R2018a, MathWorks, US).

After the experiment with each hemisphere on each recording day, the participants completed a NASA Task Load Index (NASA-TLX) questionnaire (Hart et al. 1988). The questionnaire consists of 6 items on self-perceived mental demand, physical demand, temporal demand, performance, effort, and frustration level. Participants gave a score ranging between 0 to 100 to each item, with a higher score indicating a higher subjective workload. Each participant was also required to report the strategies that they used during the neurofeedback training, which were tabulated by the experimenter.

Data analysis

Visual cursor movement
The trajectory of the basketball movement and the final vertical position of the basketball for each individual trial were recorded. The final vertical position was normalized to 0-100, with 0 and 100 indicating the bottom and top of the screen, respectively. The difference between the final vertical positions of the basketball between the ‘Training’ and ‘No Training’ conditions indicates the within-subjects effect of the neurofeedback training. In addition, how the difference in the basketball’s final vertical positions between these two conditions varied across experimental runs and different training days indicates the learning effect with the training.

Motor performance

We quantified the reaction time (RT) of the cued pinch movement in order to investigate the effect of neurofeedback training on movement initiation. Force measurements from individual trials were visually inspected and those trials with movements before the Go cue and those in which the participants failed to pinch within 2 seconds of the imperative cue were excluded. The measured force was first band-pass filtered between 0.5-20 Hz using a 4th order zero-phase digital filter and then segmented into 4 s epochs extending between 1-s prior to and 3-s after the Go cue. We then calculated a threshold by taking the mean plus 3 times the standard deviation (SD) of a segment of 500-ms force data before the Go cue of the pinch task. Next, the time delay between the Go cue and the time point when the force crossed the determined threshold was derived as the RT for the trial.

EEG beta power and beta bursts

The EEG from the targeted channel (‘C3’ or ‘C4’, contralateral to the hand performing the pinch movements) was further analysed off-line with Matlab (v2018a, MathWorks, US). These signals were first band-pass filtered between 0.5-100 Hz and notch filtered at 50 Hz.
using a 4th order zero-phase digital filter. We then segmented these data into 10-s epochs extending from 4-s prior to and 6-s after the onset of the basketball movement. Time-frequency decomposition of individual trial data was obtained by continuous complex Morlet wavelet transformation with a linear frequency scale ranging from 1 Hz to 95 Hz and a linearly spaced number (4-8) of cycles across all calculated frequencies. The time-course of the average power of the selected beta band was calculated for each individual trial. Average beta power and two beta burst characteristics (burst rate per second and accumulated burst duration) during the neurofeedback phase and during the 2-s pre-Go cue time window were calculated as described in Tinkhauser et al., 2017a for each individual trial. This enabled comparison of average beta power and burst characteristics between the ‘Training’ and ‘No Training’ conditions, and also between the ‘Real Feedback’ group and the ‘Sham Feedback’ group. In order to investigate whether there would be a similar impact of neurofeedback training on the bursts in other non-targeted frequency bands, we repeated the burst detection procedure and analyses in two other frequency bands by shifting the centre frequency band by 8 Hz down and up, to give “beta-8 Hz” and “beta+8 Hz” frequency bands.

**Statistical analysis**

2×2 ANOVAs with experimental trial conditions (‘Training’ and ‘No Training’) as a within group factor and feedback authenticity (‘Real Feedback’ and ‘Sham Feedback’) as a between group factor were used to evaluate the effect of the neurofeedback training conditions, feedback authenticity, and their interaction on the motor task RT and the modulation of average beta power and the beta burst characteristics. The assumption of sphericity was checked with Mauchly’s test, and, if violated, $F$ and $p$ values with the Greenhouse-Geisser correction were reported. Paired and unpaired bootstrapped $t$-tests (1000 permutations) were used for further *post-hoc* analyses for the comparisons of within and between group
measurements, respectively. Bonferroni correction was applied to adjust for multiple comparisons.

Each participant performed the task with both the left and right hemispheres and the contralateral hands separately. The targeted beta frequency bands were separately calibrated for the two hemispheres, and the participants were instructed that they could have different strategies for different hemispheres. The difference in the final position of the basketball between ‘Training’ and ‘No Training’ conditions during left hemisphere-targeted neurofeedback training did not correlate with that during right hemisphere-targeted neurofeedback training (Fig. 2A, \( r = 0.297, p = 0.405 \), Pearson’s linear correlation), suggesting that the performance of neurofeedback training in the two hemispheres within the same participant was relatively independent. Therefore, we have treated the recordings from different hemispheres as independent samples.

Linear mixed effects regression modelling (LME, implemented using the Matlab function `fitlme`) was used to evaluate the relationship between RTs and average beta power and the beta bursts characteristics. The LME was also used to assess the potential learning effect across different training days. In each multilevel linear model, data from all valid individual trials in both experimental trial conditions (‘Training’ and ‘No Training’) from all tested hemispheres were considered. The slope(s) between the predictor(s) and the dependent variable were set to be fixed across all hemispheres; a random intercept was set to vary by hemisphere.

**Results**
The participants were able to control the position of the visual cursor driven by cortical beta bursts.

For the ‘Real Feedback’ group, the basketball’s final vertical position averaged across all trials over all three recording days was significantly higher in the ‘Training’ condition than that in the ‘No Training’ condition ($t_{19} = 7.922$, $p = 1.939e-07$, paired $t$-test) (Fig. 2B), suggesting a control of the position of the visual cursor with veritable neurofeedback training.

For the ‘Real Feedback’ group, the basketball’s final vertical position averaged across all trials over all three recording days was significantly higher in the ‘Training’ condition than that in the ‘No Training’ condition ($t_{19} = 7.922$, $p = 1.939e-07$, paired $t$-test) (Fig. 2B), suggesting a control of the position of the visual cursor with veritable neurofeedback training.

Note that in the ‘Sham Feedback’ group, the presented basketball’s final vertical position in the ‘Training’ condition was also significantly higher than that in the ‘No Training’ condition ($t_{19} = 4.940$, $p = 9.097e-05$, paired $t$-test) (Fig. 2C). This was by design, and was achieved by setting a higher threshold in the ‘Training’ condition than the ‘No Training’ condition so that the basketball was less likely to drop in the ‘Training’ condition, in order to reduce frustration in the ‘Sham Feedback’ group. Based on the recorded EEG data, we re-calculated the positions of the basketball offline for the ‘Sham Feedback’ group to see what the difference in the final basketball positions would have been if they were calculated from the EEG recorded directly from the same participants. A 2 x 2 ANOVA (Ball Position: ‘Presented’ and ‘Recalculated’; Condition: ‘Training’ and ‘No Training’) on the ‘Sham Feedback’ group identified a significant effect of condition (‘Training’ vs ‘No Training’: $F_{1, 38} = 30.54; p = 2.54e-06$), but no effect of whether the position was ‘presented’ during the main experiment or ‘re-calculated’ post-hoc ($F_{1, 38} = 0.990; p = 0.326$), nor significant interaction between the factors ($F_{1, 38} = 0.267; p = 0.609$). As shown in Fig. 2D, the final position of the basketball re-calculated post-hoc in the ‘Training’ condition was also significantly higher than ‘No Training’ condition ($t_{19} = 3.167$, $p = 0.005$, paired $t$-test), suggesting that the ‘Sham Feedback’ group did engage in various mental strategies which also reduced beta bursts. The ‘Sham feedback’ did reflect the average beta reduction due to the mental strategies but the exact timing of the basketball movements did not match the
presence of beta bursts. An additional 2 x 2 ANOVA (Group: ‘Real Feedback’ and ‘Sham Feedback’; Condition: ‘Training’ and ‘No Training’), for the ball positions (recalculated post-hoc for the ‘Sham Feedback’ group) revealed a significant interaction between the condition (‘Training’ vs ‘No Training’) and group (‘Real Feedback’ or ‘Sham Feedback’): $F_{1,38} = 6.49, p = 0.015$. This interaction suggests that the ‘Real Feedback’ group outperformed the ‘Sham Feedback’ group in terms of suppressing beta bursts, even though the Sham Feedback group were also able to successfully use mental strategies to reduce beta bursts. To investigate whether the neurofeedback control of the basketball position was achieved by actual physical movements executed during training, we investigated the EMG and accelerometer measurements. No significant difference between the ‘Training’ and ‘No Training’ conditions was observed in the rectified EMG activities for either the ‘Real Feedback’ ($t_{19} = 0.006, p = 0.995$, paired $t$-test) or the ‘Sham Feedback’ ($t_{19} = -1.545, p = 0.139$, paired $t$-test) groups, suggesting that the neurofeedback control of the basketball position was not achieved by physical movement.

There was no significant difference between the ‘Real Feedback’ and ‘Sham Feedback’ groups in terms of self-reported task load such as mental demand, physical demand, performance and frustration, measured by the NASA-TLX questionnaire scores (Fig. 2E). Both groups reported similar strategies during the neurofeedback phase, as shown in Fig. 2F, with imaginary movement most often reported in both groups. However other strategies, such as ‘concentrating on the ball’, ‘imaging the sound made by a ball’, and ‘clearing the mind’ were also reported.

Neurofeedback training led to reduced beta bursts in motor cortex EEG
Correlational analysis with Pearson’s linear correlation confirmed that for the ‘Real Feedback’ group, the basketball’s final vertical position negatively correlated with the rate of beta bursts ($r = -0.687, p = 9.716e-07$), accumulated duration of beta bursts ($r = -0.711, p = 2.666e-07$), and with the average beta power ($r = -0.356, p = 0.024$) during the neurofeedback phase (Fig. 3A). 2×2 ANOVAs (condition (2): ‘Training’ and ‘No Training’; group (2): ‘Real Feedback’ and ‘Sham Feedback’) on average beta power and the beta burst characteristics revealed a significant main effect of condition in reducing the rate of beta bursts ($F_{1, 38} = 23.79, p = 1.943e-05$), the accumulated duration of beta bursts ($F_{1, 38} = 29.97, p = 2.989e-06$), and the average beta power ($F_{1, 38} = 36.78, p = 4.641e-07$) during the neurofeedback phase. There was also a significant interaction between the condition (‘Training’ vs ‘No Training’) and group (‘Real Feedback’ or ‘Sham Feedback’) on the rate of beta bursts ($F_{1, 38} = 6.96, p = 0.012$), the accumulated duration of beta bursts ($F_{1, 38} = 6.13, p = 0.018$), and the average beta power ($F_{1, 38} = 8.61, p = 0.006$). Post-hoc analysis with paired t-tests confirmed significant effects of the neurofeedback training in reducing the rate of beta bursts ($t_{19} = -4.851, p = 1.109e-04$), the accumulated duration of beta bursts ($t_{19} = -5.437, p = 3.026e-05$), and the average beta power ($t_{19} = -6.031, p = 8.407e-06$), in the ‘Real Feedback’ group, as shown in Fig. 3B. However, there were no similar effects in the ‘Sham Feedback’ group.

In order to investigate whether there were similar changes in other frequency bands, we repeated these tests in the ‘Beta-8Hz’ (mean ± SEM: 11.10 ± 0.52 Hz and 11.20 ± 0.57 Hz for the ‘Real Feedback’ and ‘Sham Feedback’ groups, respectively, maximum frequencies were 16 Hz for both groups) and ‘Beta+8Hz’ (mean ± SEM: 27.10 ± 0.52 Hz and 27.20 ± 0.57 Hz for the ‘Real Feedback’ and ‘Sham Feedback’ groups, respectively, maximum frequencies were 32 Hz for both groups) frequency bands. The results showed no interaction between group (‘Real Feedback’ and ‘Sham Feedback’) and condition (‘Training’ and ‘No
Training’) on the burst characteristics and average power in the ‘Beta-8Hz’ frequency band, but an interaction on average power ($F_{1,38} = 17.18, p = 0.0002$) in the ‘Beta+8Hz’ frequency band. Due to space limitation, the figures of these results are not shown. Post-hoc analysis further showed a significant reduction of average power in the ‘Training’ condition compared with the ‘No Training’ condition in the ‘Real Feedback’ group ($t_{19} = -3.897, p = 9.691e-04$), not in the ‘Sham Feedback’ group ($t_{19} = 1.746, p = 0.097$) in the ‘Beta+8Hz’ frequency band.

There were no other differences: For the accumulated burst durations in the other tested frequency bands in the ‘Real Feedback’ group (‘Beta-8Hz’: $t_{19} = -2.505, p = 0.022$; ‘Beta+8Hz’: $t_{19} = -1.395, p = 0.179$) or the ‘Sham-Feedback’ group (‘Beta-8Hz’: $t_{19} = -1.677, p = 0.110$; ‘Beta+8Hz’: $t_{19} = 1.258, p = 0.224$).

In order to evaluate whether there was any sustained carry-over effect of neurofeedback training, we repeated the abovementioned tests on the beta burst characteristics and averaged beta power quantified during the 2 second pre-Go cue time window when the visual feedback was no longer available. A significant interaction between the experimental condition and group was confirmed for the accumulated duration of beta bursts ($F_{1,38} = 4.92, p = 0.033$), suggesting a sustained carry-over effect of neurofeedback training in reducing the accumulated beta burst duration, but only for the ‘Real Feedback’ group. No other comparisons reached significance.

**Neurofeedback training reduced reaction times in subsequently cued movements**

The average reaction time in response to the Go cue was significantly reduced in the ‘Training’ condition compared with the ‘No Training’ condition, as confirmed by a significant main effect of experimental trial condition ($F_{1,38} = 18.93, p = 9.84e-5$) in the 2×2 ANOVAs, which also revealed a significant interaction between condition and group ($F_{1,38} =$
Post-hoc analysis further confirmed that only ‘Real Feedback’ group showed a significant RT reduction (0.319 ± 0.009 for the ‘Training’ condition compared to 0.349 ± 0.010 s for the ‘No Training’ condition, $t_{19} = -5.089$, $p = 6.519e-05$, paired $t$-test, Fig. 4A). In contrast, there was no significant difference in the reaction time between the ‘Training’ and ‘No Training’ conditions for the ‘Sham Feedback’ group (0.328 ± 0.013 compared to 0.336 ± 0.012 s, $t_{19} = -1.271$, $p = 0.2191$, paired $t$-test, Fig. 4B). This was not due to different baseline levels in these two groups, as no significant difference was observed between the ‘Real Feedback’ and ‘Sham Feedback’ groups for RTs in the ‘No Training’ condition ($t_{38} = 0.837$, $p = 0.408$, un-paired $t$-test).

The reaction time in cued movement correlated with beta burst characteristics before the Go cue

When all participants in both feedback groups were considered together, there were positive significant cross-hemisphere correlations between the average RT in the subsequent cued movements and the beta burst characteristics during the 2-s before the Go cue in both the ‘No Training’ condition ($N = 40$, $r = 0.42$, $p = 0.007$ and $r = 0.479$, $p = 0.002$ for the rate and accumulated duration of beta bursts, respectively) and the ‘Training’ condition ($N = 40$, $r = 0.45$, $p = 0.004$ and $r = 0.519$, $p = 6.02e-4$ for the rate and accumulated duration of beta bursts, respectively. Fig. 5A). When the beta bursts characteristics during the neurofeedback phase (6.5 to 2.5 s in average before the Go cue) were considered, the correlations with subsequent RT were positive but not significant (shown in Fig. 5B).

However, the average RT did not correlate with the average beta power either during the 2-s period before the Go cue (‘No Training’: $N = 40$, $r = 0.172$, $p = 0.29$; ‘Training’: $N = 40$, $r = \ldots$
0.17, \( p = 0.295 \) or during the neurofeedback phase (‘No Training’: \( N = 40, r = -0.031, p = 0.849 \); ‘Training’: \( N = 40, r = -0.013, p = 0.936 \)).

LME modelling considering all individual trials was used to further assess whether there were consistent trial-to-trial correlations between RT and beta characteristics within each tested hemisphere. This revealed significant within-hemisphere correlations between RTs and the accumulated duration of beta bursts during the 2s pre-Go cue phase \( (k = 0.024, p = 2.500\text{e-09}) \) and the neurofeedback phase \( (k = 0.006, p = 0.005) \), indicating that more accumulated duration of beta bursts in the motor cortex before the Go cue predicts prolonged RT on trial-to-trial basis. In contrast, there was no significant effect of average beta power during the neurofeedback phase or the 2s pre-Go cue phase in predicting RT.

Furthermore, the difference between RTs in the ‘Training’ and ‘No Training’ conditions significantly correlated with changes in the accumulated duration of beta bursts during the 2-s pre-Go cue phase across all tested hemispheres (Pearson’s linear correlation: \( r = 0.435, p = 0.005, \text{Fig. 6A} \)) and during the 4-s neurofeedback phase (Pearson’s linear correlation: \( r = 0.375, p = 0.017, \text{Fig. 6B} \)). These results suggest that the hemispheres that achieved a greater reduction in beta burst characteristics were associated with greater improvement in motor initiation in the contralateral hand evidenced by improved RTs. Within each hemisphere, successful beta burst suppression before the Go cue predicted faster RTs on a trial-to-trial basis. In contrast, there was no significant within-hemisphere correlation between RTs and the accumulated burst duration in the ‘Beta-8Hz’ or ‘Beta+8Hz’ frequency bands.

**Learning effect of neurofeedback training**
In order to investigate whether there were any learning effects across experimental runs and training days, we quantified the difference in the basketball’s final positions in the ‘Training’ and ‘No Training’ conditions for different experimental runs and different days in the ‘Real Feedback’ group. On Day 1, there was a progressive increase in the difference in the basketball position across the four experimental runs. This was accompanied by a progressive difference in the RT between the conditions (Fig. 7A), with a significant effect of experimental run number \( (k = -0.013, p = 0.040) \) identified by the LME modelling. There was no learning effect across different experimental runs on Day 1 in the ‘Sham Feedback’ group \( (k = -0.012, p = 0.096) \).

Across different training days, we noticed a ceiling effect in learning: by performing a quantile split for participants in the ‘Real Feedback’ group, we observed that for the 25% hemispheres with best performance on the first day, there was no cross-day learning effects. On the other hand, for the remaining 75% hemispheres, there was significant improvement in the neurofeedback cursor control from Day 1 to Day 3 (Fig. 7B, \( t_{14} = -2.559, p = 0.023 \)), and this was accompanied by an increase in the difference in RTs over days, which was not observed in the ‘Sham Feedback’ group. In addition, self-reported mental demand progressively reduced with training days for both ‘Real Feedback’ and ‘Sham Feedback’ groups, indicating another learning effect (Fig. 7C).

**Discussion**

In this double-blind sham-controlled study, we used a sequential neurofeedback-behaviour task paradigm to train healthy subjects to self-suppress beta bursts in the sensorimotor cortex before a cued finger movement. The online visual feedback in the paradigm took into account the temporal dynamics of the sensorimotor beta activity, and specifically targeted high
amplitude beta bursts. The rate of beta bursts and accumulated duration of beta bursts, as well as the average beta power in the sensorimotor cortex were significantly reduced with ‘Real Feedback’ training but not with ‘Sham Feedback’ training. The ‘Real Feedback’ group also showed a reduction in reaction times in subsequent cued movements. Considering all individual trials across all tested hemispheres, the reaction time positively correlated with the rate and accumulated duration of beta bursts before the Go-cue, but not with average beta power. The changes in the accumulated duration of beta bursts induced by neurofeedback training positively correlated with the shortening of reaction time. These results are consistent with previous studies which demonstrated a positive correlation between beta bursts and reaction time (Little et al., 2019; Wessel 2019), but as we purposefully modulated beta bursting through neurofeedback we also provide evidence in favour of a causal link between transient beta bursts and motor function.

Improved neurofeedback

Here we show that the healthy participants gained control of the beta band neural oscillations measured using EEG with the help of neurofeedback training within three training days, and the self-reported mental load progressively reduced over days. Real-time functional MRI (rtfMRI) and EEG are the most often used imaging modalities for neurofeedback training. It has been noted that EEG neurofeedback requires many sessions of training for a participant to alter electrical activity (Boulay et al., 2011; Erickson-Davis et al. 2012; McFarland et al., 2015), compared with rtfMRI in which participants can selectively modify the fMRI blood-oxygen-level dependent (BOLD) signal within a few sessions of training (Subramanian et al. 2011, 2016; Thibault et al., 2016). This may be due to the lower signal to noise ratio in the EEG measurements and the fast time dynamics in the signal of interest. Synchrony in the beta frequency band in the motor cortex or in the basal ganglia takes the form of bursts of
different durations and amplitudes (Shin et al., 2017; Tinkhauser et al., 2017a, 2017b).

Directly translating continuously updated beta-band power into visual feedback can lead to a flickering, dynamic feedback which can be confusing for participants. Limiting the update rate, averaging data over a time window of seconds in duration, and converting continuous measurements of power into a binary visual display are often used strategies to smooth the feedback signal in EEG neurofeedback. In our paradigm, we calculated the beta band power within a 500 ms window from EEG recordings and updated the visual feedback every 250 ms. This was based on previous studies showing that long beta bursts (over 500 ms) are more closely related to motoric impairment in Parkinson’s disease. By taking into account the temporal dynamics of the signal of interest, and reducing the variance and noise in the visual feedback that are not behaviourally relevant, our paradigm allowed healthy participants to learn to suppress beta power within 30 min of training.

This is the first double-blind sham-controlled study, to our knowledge, showing that veritable neurofeedback helped participants learn to suppress cortical beta bursts better than sham-feedback, and accordingly, real neurofeedback training led to more behavioural benefit in speeding up movement initiation than sham feedback. Training protocols that teach people to modulate brain activities have been suggested to constitute a promising approach to motor rehabilitation for people with strokes and other disorders (Huster et al. 2014; McFarland et al. 2015).

Sham control in neurofeedback studies

Even though the sham control is important to confirm the effect of veritable neurofeedback on observed behavioral alterations compared to other mental strategies (Thibault et al. 2015; 2016), just how one should provide a proper sham control is not an easy question in
neurofeedback studies. No feedback (Subramanian et al., 2011; Boe et al., 2014) or random feedback (Ramos-Murguialday et al., 2013; Ono et al., 2018) have been used as controls in other neurofeedback studies. In the current study, the feedback provided to the control group was calculated based on a replay of resting EEGs previously recorded from other healthy participants who did not participate in this study. This choice was made based on the following considerations. First, the double-blinded design was critical in this study in order to make sure all participants made similar effort in the task and to make sure that the study would not be biased due to the difference in the experimenter’s instructions and attitude. It would have been impossible to blind the participants or the experimenter if we had provided ‘No Feedback’ to the control group, as both the participants and the experimenter would be aware of the group assignment of the participants. For similar reasons, we did not use the EEGs recorded from the ‘Real Feedback’ group for the replay for the ‘Sham Feedback’ group, because this would require the ‘Real Feedback’ and ‘Sham Feedback’ groups to be recorded in a specific order, making double-blinded design impossible. Third, without any feedback, visual attention to moving objects might induce a reduction in beta band activities in the ‘Real Feedback’ group, but not the control group (Li et al., 2015). So we used the replay of previously recorded EEGs in order to match the dynamics in the visual feedback provided to the ‘Sham Feedback’ and ‘Real Feedback’ groups, which would also help control other placebo effects. Finally, real physiological EEG signals are very different compared with random signals, and thus it would be difficult to maintain similar stationarity and variability in the visual feedback for both groups if we generated feedback randomly for the control group.

It is possible that sham feedback might have interfered with the mental strategies used by the participants in the ‘Sham Feedback’ group. We addressed this by changing the ‘threshold’ to
trigger the basketball movement so that the basketball was less likely to drop in the ‘Training’ condition than the ‘No Training’ condition. This ‘Sham’ control was necessary for the double-blinded design, as neither the experimenter nor the participants were aware of the experimental conditions. Post-hoc analysis showed that the final position of the basketball calculated based on actual EEGs from the participants in the ‘Sham Feedback’ group was also significantly higher in the ‘Training’ condition than the ‘No Training’ condition, suggesting that the ‘Sham Feedback’ group did engage in various mental strategies which also reduced beta bursts. In addition, the levels of beta reduction in the ‘Sham Feedback’ group were similar to those observed in other studies on beta reduction during motor imagery (McFarland et al., 2000; Nam et al., 2011). There was no significant difference between the ‘Sham Feedback’ and ‘Real Feedback’ groups in terms of self-reported mental effort as well as mental strategies used.

Post-hoc analysis showed that the average basketball positions presented during the experiments and those re-calculated offline were similar in the ‘Sham Feedback’ group. This means that the ‘Sham Feedback’ did reflect the average beta reduction due to the mental strategies employed by participants in the ‘Sham Feedback’ group. The main difference between the ‘Real Feedback’ and ‘Sham Feedback’ was whether the exact timing of the basketball movements matched with the presence of the beta bursts. Our reported interaction between the group (‘Real Feedback’ vs ‘Sham Feedback’) and experimental condition (‘Training’ vs ‘No Training’) confirmed that veritable real-time neurofeedback had additional effects in training the participants to learn the ‘skill’ of suppressing beta bursts. This is consistent with our results in Fig. 7A, B showing that only in the ‘Real Feedback’ group did performance improve across experimental runs and across training days. More importantly, real neurofeedback training led to a behavioural benefit in speeding up movement initiation
more than sham feedback, suggesting an additional benefit of the real feedback compared to the sham feedback.

Is beta bursts or average beta power related to motor performance?

Movement-related power reduction before and during voluntary movement in the beta frequency band has been consistently observed at different sites in the cortical-basal ganglia motor network in both healthy subjects (Pfurtscheller et al., 1999; Tan et al., 2014a; Torrecillos et al., 2015) and patients with Parkinson’s disease (Cassidy et al., 2002; Doyle et al., 2005; Tan et al., 2014b). In particular, Kühn et al., (2004) found that the event-related desynchronization (ERD) of beta power in the human subthalamic nucleus correlated with motor performance, with a longer latency ERD associated with longer reaction times in an externally paced voluntary movement. Such movement-related beta power reduction has been suggested to reflect changes in the probability of beta bursts rather than a smooth modulation of sustained beta activity (Feingold et al., 2015), and more recently, it has been emphasized that the beta bursts in the cortical-basal ganglia motor network predict sensorimotor behavior (Feingold et al., 2015; Sherman et al., 2016; Shin et al., 2017; Torrecillos et al., 2018; Little et al., 2019; Wessel 2019) and correlate with motor impairment in patients with Parkinson’s disease (Tinkhauser et al., 2017a, b). Indeed, beta bursts in the subthalamic nucleus, a key relay in basal ganglia-cortical circuits, are more predictive of motor impairment than average beta power in patients with Parkinson’s disease (Torrecillos et al., 2018; Tinkhauser et al., 2020), and similar observations have been made regarding cortical beta bursts and trial-averaged beta power. Little et al (2019) showed that the timing of beta bursts was a stronger predictor of single trial behaviour than single trial-averaged beta amplitude. Here we also show that the reaction time of cued movements correlates with the incidence of pre-movement beta bursts, and not with the average beta power. In addition, we show that
healthy participants can volitionally modulate the incidence of beta bursts with neurofeedback training, and this as associated with improvement in motor initiation, raising the possibility that the more direct link between motor behaviour and beta activity is with beta bursts rather than averaged levels of beta power.

The current study therefore strengthens the link between movement initiation and pre-movement beta bursts in the sensorimotor cortex; and also helps establish an association between neurofeedback training and enhanced performance in terms of both self-regulation of pre-movement beta bursts and movement initiation. Thus, this study emphasises the importance of better characterizing the temporal dynamics of the targeted brain activity when using neurofeedback training to change behaviour.

Detecting beta bursts in real-time and other limitations

In this study, we used a threshold technique applied to the average beta power over the last 500 ms time window to define the presence of absence of beta bursts in real-time. In order to take into account any potential drift in baseline beta activity, we quantified the threshold as the 75th percentile value of the averaged beta power over 500 ms time windows recorded while participants were at rest before each experimental run. Cortical beta bursts are reported to have shorter durations than the 500 ms window used in our real-time analysis (Shin et al., 2017; Sherman et al, 2016). Nevertheless the incidence of the ‘beta bursts’ detected in real-time, indicated by the vertical position of the visual cursor use in the paradigm correlated well with the beta burst rate quantified in post-processing (Fig. 3A), with the vertical position of the visual cursor capturing around 50% of the variance in beta burst characteristics revealed by post-processing using more conventional burst-identifying techniques, such as those reported by Tinkhauser et al (2017a, 2017b). The 500 ms time window for quantifying
beta power in real-time used here afforded a compromise whereby excessive flickering was
avoided but sensitivity of neurofeedback was maintained. In the future it would be
worthwhile investigating whether other beta burst-detection methods might be more efficient
in real-time.

Another limit of the study is: the current paradigm aims to give feedback about the
occurrence of beta bursts, therefore, the visual cursor (the basketball displayed on the screen)
can only drop down once a beta burst is detected but cannot rise up again. Thus, the visual
cursor might have already dropped to the bottom of the screen before the end of the trial,
making the participants stop trying before the end of trial. The neurofeedback paradigm may
be further improved by allowing the visual cursor to rise again if beta bursts were suppressed
successfully.

Summary

In this double-blind sham-controlled EEG neurofeedback study, we showed that veritable
neurofeedback training can help participants learn to suppress beta bursts in motor cortex,
and this was associated with speeding up in movement initiation in response to a subsequent
Go-cue. The ability of beta burst self-modulation was significantly higher with veritable
feedback than with sham feedback, and the improvement in movement initiation was only
observed with veritable feedback. These results provide evidence of a causal link between
pre-movement beta bursts and delayed movement initiation. The study also suggests
neurofeedback training targeting beta bursts may be an effective approach to improve
movement initiation.

Figure 1: Experimental protocol. (A) Timeline of one individual trial. Each trial consisted of a neurofeedback phase followed by a cued pinch movement. After the finger pinch motor task, a message was displayed (‘Well done!’ or ‘Could be better!’) depending on whether the reaction time of the previous movement was shorter or longer than 500 ms. If movement onset was not detected within 2 s after the Go cue, the message ‘Missed!’ was displayed. For the ‘Real Feedback’ group, beta bursts were detected in real-time and used to drive the movement of the basketball in the neurofeedback phase based on EEG signals recorded from the motor cortex contralateral to the hand performing the pinch movements. For the ‘Sham Feedback’ groups, the beta bursts were calculated based on a replay of EEG signals recorded from other participants. (B) The timeline of one experimental run which consisted of 30 s of resting, and one block of 10 continuous ‘Training’ trials and one block of 10 continuous ‘No Training’ trials. The instruction for each block was presented for 10 s before the block starts. The order of the ‘Training’ and ‘No Training’ blocks was randomised. At the beginning of each experimental run the threshold was recalculated based on recordings made at rest.

Figure 2: The neurofeedback training performance and the self-reported task load and strategies. (A) The performance of the neurofeedback control, quantified by the difference in the basketball’s final positions between ‘Training’ and ‘No Training’ conditions, using the left hemisphere (“C3”) did not correlate with that using the right hemisphere (“C4”) within the same participant in the ‘Real Feedback’ group. (B) In the ‘Real Feedback’ group, participants were able to control the position of the basketball with its final position significantly higher in the ‘Training’ condition, T, compared to ‘No Training’ condition, N. (C) The differences in the basketball’s final positions (presented online) between the ‘Training’ and ‘No Training’ conditions were also significant for the ‘Sham Feedback’ group. (D) The basketball’s final position for the ‘Training’ and ‘No Training’ conditions would also have been significantly...
different if they had been calculated based on the EEGs measured in real-time. Results for each individual hemisphere were shown in the plots on the left, with the dots and crosses indicating the individual averages and SEMs. The shading of the dots indicates the difference between ‘No Training’ and ‘Training’ conditions, with darker blue and orange indicating higher measurement in the ‘Training’ and ‘No Training’ conditions, respectively. The X axis of the histogram on the diagonal refers to the difference between ‘No Training’ and ‘Training’ conditions (‘N-T’) and the Y axis refers to the number of cases. The red dotted line indicates zero. Bar plots on the right show the group averages (mean ± SEM, ***p<0.001). (E) The NASA-TLX scores given by the subjects suggested that there was no difference in self-reported task load between real and sham feedback groups. (F) Similar strategies for controlling the ball’s movement were reported by the participants in real and sham groups.

**Figure 3** (A) In the ‘Real Feedback’ group, the basketball’s final vertical position strongly correlated with the rate (left) and accumulated duration (middle) of beta bursts, and also weakly correlated with the baseline normalized average beta power during the ‘feedback phase’. (B) Burst rate (left) and accumulated burst duration (middle), as well as the average beta power (right) during the neurofeedback phase were significantly reduced during ‘Training’ condition, T, compared with ‘No Training’ condition, N, in ‘Real Feedback’ group, not in ‘Sham Feedback’ group. The bar plots with error bars show the mean and SEM across tested hemisphere. The dot plots show data from individual hemispheres with the dots and crosses indicating the individual averages and SEMs. The shading of the dots indicates the difference between ‘No Training’ and ‘Training’ conditions, with darker blue and orange indicating higher measurement in the ‘Training’ and ‘No Training’ conditions, respectively. The X axis of the histogram on the diagonal refers to the difference between ‘No Training’ and ‘Training’ conditions (‘N-T’) and the Y axis refers to the number of cases. The red dotted
line indicates zero. Bonferroni correction was applied for multiple comparisons. Values are presented as mean ± SEM; ***$p<0.001/3$.

Figure 4: Real neurofeedback training sped up the reaction time in subsequently cued movement, but not ‘sham feedback’. (A) The reaction time for each individual hemisphere (left) and group-averaged reaction time (right) in ‘Training’, T, and ‘No Training’ conditions, N, during real feedback. (B) The reaction time for each individual hemisphere (left) and group-averaged reaction time (right) in ‘Training’ and ‘No Training’ conditions during sham feedback. The dots with crosses indicate the means and cross-trial SEMs for each tested hemisphere (some data points appear to have no error bars because the lines corresponding to SEMs are shorter than the diameter of the point). The shading of the dots indicates the difference between ‘No Training’ and ‘Training’ conditions, with darker blue and orange indicating higher measurement in the ‘Training’ and ‘No Training’ conditions, respectively. The X axis of the histogram on the diagonal refers to the difference between ‘No Training’ and ‘Training’ conditions (‘N-T’) and the Y axis refers to the number of cases. The red dotted line indicates zero. The error bar plots show the mean and SEM across all tested hemisphere in different conditions. ***$p<0.001$.

Figure 5: The reaction time of the cued pinch movements correlated with the beta burst characteristics before the Go-cue, but not the average beta power. (A) There were significant positive cross-hemisphere correlations between the RT and burst characteristics during the 2-s before the go cue in both the ‘Training’ and ‘No Training’ conditions. In contrast, there was no significant correlation between RT and average beta power during the same time window. Each point indicates data from one individual hemisphere. Here the beta power was baseline normalized against the average power during 30-s resting period at the
beginning of each experimental run. The red and green points indicate hemispheres from the ‘Real Feedback’ and ‘Sham Feedback’ groups, respectively. (B) When the burst characteristics during the ‘neurofeedback phase’ (6.5 to 2.5 s in average before the Go cue) were considered, the relationship with RT were positive, but not significant.

Figure 6: The reduced reaction times in the ‘Training’ trials compared to ‘No Training’ trials positively correlated with the reduced accumulated beta burst duration during the 2-s pre-cue periods (A) and during the 4-s ‘feedback phase’ (B). Each point indicates data from one tested hemisphere. The red and green points indicate hemispheres from the ‘Real Feedback’ and ‘Sham Feedback’ groups, respectively.

Figure 7: The learning effect of neurofeedback training was achieved across experimental runs and across training days. (A) The averaged difference in the basketball position (upper) and the reaction time (middle) between ‘Training’ and ‘No Training’ conditions across four experimental runs (S1 – S4) on the first training days for all hemispheres in the ‘Real Feedback’ group, and the difference in the reaction time for the ‘Sham Feedback’ group (bottom). (B) The averaged difference in the basketball position (upper) and the reaction time (middle) between ‘Training’ and ‘No Training’ conditions across three training days (D1 – D3) for those 75% hemispheres with the worst training effect on the first day in the ‘Real Feedback’ group. The bottom subplot column indicates the averaged difference in reaction time between ‘Training’ and ‘No Training’ conditions for the 75% hemispheres with the worst training effect on the first day in the ‘Sham Feedback’ group. (C) Self-reported mental demand scores decreased over the training days in both ‘Real Feedback’ and ‘Sham Feedback’ groups, but no significant difference was observed between these two groups.
