ABSTRACT

Triticeae species, including wheat, barley, and rye, are critical for global food security. Mapping agronomically important genes is crucial for elucidating molecular mechanisms and improving crops. However, Triticeae includes many wild relatives with desirable agronomic traits, and frequent introgressions occurred during Triticeae evolution and domestication. Thus, Triticeae genomes are generally large and complex, making the localization of genes or functional elements that control agronomic traits challenging. Here, we developed Triti-Map, which contains a suite of user-friendly computational packages specifically designed and optimized to overcome the obstacles of gene mapping in Triticeae, as well as a web interface integrating multi-omics data from Triticeae for the efficient mining of genes or functional elements that control particular traits. The Triti-Map pipeline accepts both DNA and RNA bulk-segregated sequencing data as well as traditional QTL data as inputs for locating genes and elucidating their functions. We illustrate the usage of Triti-Map with a combination of bulk-segregated ChIP-seq data to detect a wheat disease-resistance gene with its promoter sequence that is absent from the reference genome and clarify its evolutionary process. We hope that Triti-Map will facilitate gene isolation and accelerate Triticeae breeding.

Key words: agronomic gene mapping, Triticeae, wheat, bulk-segregated ChIP-seq, Triti-Map

INTRODUCTION

Triticeae species, including wheat and barley, are among the major food crops. Transposable element bursts before and after the divergence of Triticeae species have contributed to their large genome sizes (Wicker et al., 2018). For example, the worldwide staple common wheat has a genome size of 16 Gb (International Wheat Genome Sequencing Consortium (IWGSC) et al., 2018). In addition, Triticeae species have complex genomes, and many wild relatives with desirable agronomic traits have been deployed for crop improvement. Distant hybridizations and introgressions have occurred frequently during evolution and domestication of Triticeae, as well as...

modern breeding processes (Feldman and Levy, 2012). The considerable size and complexity of the genomes of these species are substantial obstacles for researchers trying to localize genes or functional elements that control specific agronomic characteristics.

Recently developed mapping methods (e.g., bulked segregant analysis [BSA]) have significantly decreased the cost and labor associated with genetic research (Zou et al., 2016). Combining BSA with RNA sequencing (RNA-seq) and exome-seq methods has further lowered the total cost of map-based cloning (Hill et al., 2013; Miller et al., 2013). Several modified strategies based on BSA have enhanced genetic analysis via improved sequence assembly or optimized calculations (Abe et al., 2012; Takagi et al., 2013a; Fekih et al., 2013). The accuracy and resolution of map-based cloning depend on the accuracy and distribution of genetic markers that are heterogeneous among populations. Table 1 lists the advantages and disadvantages of different sequencing strategies used to obtain molecular markers in terms of overcoming these obstacles. These segregant strategies have facilitated the detection of essential loci that control target traits.

For Triticeae species with extensive and frequent introgression, however, gene mapping is confronted with the following difficulties:

1. High computational cost due to the large genome. Specific packages and optimized parameters are needed to overcome the obstacles presented by the large genomes.

2. The causal gene may not be present in the reference genome within the candidate region. Two strategies may be used. The first is to collect syntenic regions and genes from other Triticeae genomes. The second is to enrich functional regions by RNA-seq or chromatin immunoprecipitation sequencing (ChiP-seq), followed by sequencing and de novo assembly. A recent report demonstrated that a large fraction of genes and regulatory elements could be captured by ChiP-seq without relying on reference genome sequences (Qi et al., 2018).

3. The causal loci may be present in the regulatory region. For example, a recent report on barley revealed that the deletion of one “TA” short tandem repeat in the promoter region was sufficient to confer the six-rowed trait (Wang et al., 2021). The large intergenic regions in Triticeae genomes have a substantial abundance of regulatory elements. To identify the regulatory region and the gene region simultaneously, a new strategy involving the use of ChiP-seq technology to capture the core genome was recently proposed (Qi et al., 2018).

4. Because of the generally significant linkage disequilibrium of Triticeae, gene mapping strategies tend to result in large candidate regions, and functional annotation is required to narrow down candidate genes or elements based on multi-omics information. Tissue specificity and specific responses to certain treatments may provide important clues about the causal gene or element, and these require well-processed and organized multi-omics data.

In this study, we introduce Triti-Map, a tool for efficient gene mapping based on bulk-segregated DNA- or RNA-seq data and quantitative trait loci (QTL) data from Triticeae. Triti-Map contains a series of computational packages specifically optimized for Triticeae species, together with a web interface that integrates multi-omics data from Triticeae, to maximize the mining of public data and sequencing results to identify candidate genes. We illustrate how Triti-Map may be used to locate candidate genes that control disease resistance based on the bulked segregant ChiP-seq method, making it an easy-to-use resource for efficient gene mapping in Triticeae species.

RESULTS

Computational modules of Triti-Map for locating candidate intervals and detecting specific candidate sequences

The major obstacles to Triticeae gene mapping include their large genomes and the high frequency of introgressed genes that may not be present in reference genomes. Here, we present Triti-Map, which contains a series of computational packages and a web-based interface specifically designed and optimized for Triticeae species to narrow down candidate intervals and detect specific candidate sequences (Figure 1). Figure 1 illustrates the workflow of the Triti-Map computational modules. Triti-Map uses a pair of bulk-sequencing datasets (another pair of parental
datasets is optional) and a user-set parameter list to reveal candidate regions and sequences. Triti-Map supports the processing of segregated DNA- and RNA-sequencing results and traditional QTL data. The input data types are automatically detected and subjected to appropriate analyses.

The package uses the following analysis pipeline. In brief, the preprocessed reads are analyzed by two modules. The interval mapping module maps the reads to a reference genome, after which a traditional method is used for BSA-based interval detection. The assembly module assembles the sequenced reads to identify sequences absent in the reference genome. The assembled sequences specific to the bulk that exhibits the target trait are kept for subsequent analyses. These two computational modules (i.e., the interval mapping module and the de novo assembly module) integrate computational steps using Snakemake (Koster and Rahmann, 2012). Users only need to set the basic configuration parameters to complete the analysis and obtain candidate genomic regions and phenotype-associated sequences that are lacking in the reference genome.

The web-based annotation module of Triti-Map for locating functional genes and regulatory elements

After detecting a candidate functional interval, candidate genes or regulatory elements must be identified and localized. This is a challenging task, considering the substantial linkage disequilibrium of wheat populations and the frequency of introgressions (Cheng et al., 2019; He et al., 2019; Zhou et al., 2020). Thus, we developed a web-based platform that integrates multi-omics data, sequence data, and functional information to maximize the mining of public data and sequencing results to identify candidate genes (Figure 2A). First, to address the possibility that a causal gene may not be present in the reference genome, a comprehensive collection of colinear regions across Triticeae species, including *Hordeum vulgare*, *Aegilops tauschii*, *Triticum urartu*, *T. dicoccoides*, *T. turgidum*, and *T. aestivum*, is retrieved for any input candidate interval. Lineage-specific and shared genes as well as functional information are listed. Second, for the de novo assembled sequences specific to the bulk with the target trait (Figure 2B), functional annotation and phylogenetic analysis of sequences are performed via comparison with all publicly available sequences using the EBI RESTful application programming interface (API) to help narrow down the candidates. Third, for genes within a candidate region, a phylogenetic tree representing the gene
Plant Communications

evolutionary process is constructed, enabling users to deduce the association between the presence of a gene and a particular trait. Fourth, for SNPs that contribute to interval analyses, the potential functions and feature distributions are presented, which may help to identify functional elements.

Because the enrichment of specific epigenetic markers reflects the presence of active regulatory elements in non-coding regions, we included a search engine and a genome browser for detecting and visualizing epigenetic modifications within candidate regions or regions surrounding candidate genes and SNPs (Figure 2B).

Optimization to overcome specific challenges in Triticeae gene mapping

The pipeline was optimized in the following ways to address specific challenges in Triticeae gene mapping (Figure 3).

(1) The software and parameters were optimized to decrease the analysis time. Because of the large genomes and long chromosomes of Triticeae species, commonly used tools for analyzing genomic loci intervals (e.g., bedtools; Quinlan and Hall, 2010) are very slow. We used GIGGLE (Layer et al., 2018), which quickly compares a large number of wheat genomic intervals based on a temporal indexing scheme using a B+ tree to create a single index of the genome intervals, thereby significantly shortening the time required for analysis. To detect variants, we split the genome by chromosomes and used the Genome Analysis Toolkit (GATK) HaplotypeCaller (Van der Auwera et al., 2013) for parallel analysis. The default alignment program for DNA-seq-type sequence alignment is BWA-mem2 (Vasimuddin et al., 2019), which is faster than bwa (Li and Durbin, 2009) because of enhanced cache reuse, simplified algorithms, and the use of single instruction, multiple data (SIMD) wherever applicable. The alignment results produced by this program are identical to those of bwa.

(2) Given the frequent introgressions and distant hybridizations between Triticeae species, a candidate gene may be absent in the mapped interval of the reference genome. Triti-Map can retrieve new bulk-specific sequences via de novo assembly and comparison. Furthermore, it collects Triticeae genomic regions colinear with candidate regions and provides detailed functional annotations to increase the chances of identifying a candidate gene for a particular trait.

(3) Regarding sequence comparisons and functional annotations, because of the rapid increase in available genome sequences and multi-omics data, rather than using a local database, the pipeline uses the European Molecular Biology Laboratory-European Bioinformatics Institute (EMBL-EBI) RESTful APIs (Madeira et al., 2019) to obtain up-to-date sequence information.

Multiple strategies were used to simplify the use of Triti-Map. The software and environment required for analyses can be quickly deployed through Conda. All of the analysis modules were developed and integrated based on the Snakemake workflow management system. Moreover, the configuration is simple, flexible, and easy to use. Interval mapping (Figure 3, left) and de novo sequence assembly (Figure 3, right) can be conducted separately or together with other modules (Figure 3). The Triti-Map usage document (https://github.com/fei0810/Triti-Map/wiki) provides complete instructions and a case study.

Triti-Map and bulk-segregated ChiP-seq used to identify a disease-resistance gene and its promoter region not present in the reference genome

We next illustrate how Triti-Map and bulk-segregated ChiP-seq help to detect a disease-resistance gene that is not present in the reference genome as recently reported (Wu et al., 2021). Two bulked segregant pools were collected from the F2 progeny of a cross between Xuezao (susceptible to powdery mildew) and 3D249 (resistant to powdery mildew). For each pooled sample, a ChiP-seq analysis was performed for three histone marks (H3K4me3, H3K27me3, and H3K36me3) that are closely associated with gene activities. The sequencing data were analyzed using the interval mapping module of the Triti-Map package, resulting in the identification of a 6-Mb region on chromosome 7A (chr7A: 724,111,912–730,119,678) that is highly associated with powdery mildew resistance (Figure 4A, Supplemental Figures 1 and 2). High-quality SNPs within this region were used as input data for the Triti-Map web-based annotation module. Nonsynonymous mutations were detected in two disease resistance-related genes (TraesCS7A02G551900 and TraesCS7A02G552000). In addition, the integrated epigenetic and motif information revealed the presence of the DNase I hypersensitive site (DHS), as well as H3K36me3, H3K4me3, and H3K9ac, in the TraesCS7A02G551900 promoter, suggesting that the promoter is highly accessible to transcription factors (e.g., autonomously replicating sequence-binding factor 1 [ABF1]) (Figure 4B; Supplemental Table 2). However, the results of an experimental validation indicated that these two genes did not fully segregate with the disease-resistance trait.

We hypothesized that the candidate gene was present in other species or wheat populations but not in the reference genome. We used the assembly module to detect disease resistance-specific sequences. Among the 10,429 resistant pool-specific scaffolds, 1,704 were partially mapped to Triticeae genomic regions colinear with the candidate region using the collinearity function of the web-based annotation module (Figure 4C). A subsequent functional annotation using the EMBL-EBI hmmscan API detected nine sequences encoding protein domains common among R genes. In addition, four sequences encoding the NB-ARC (nucleotide-binding domain shared with apoptotic protease activating factor-1 [APAF-1], various R proteins, and CED-4) domain and five sequences encoding the leucine-rich repeat (LRR) domain were detected (Supplemental Table 3). The EMBL-EBI blast API of the assembly module detected sequences encoding one NB-ARC domain and one LRR domain that were highly similar (>99.7% sequence identity) to Pm60, which was originally identified as the gene responsible for powdery mildew resistance in the diploid species T. urartu (Zou et al., 2018) (Figure 4D; Supplemental Table 4). These two sequences accounted for 69% of the total length of Pm60. The Pm60 sequence was further extended using the sequencing data, resulting in a 235-bp extension at the 5' end and a 203-bp extension at the 3' end (10% of the total length of Pm60) (Qi et al., 2018). The 5' end was enriched for both active and repressive marks, indicating that this gene is in a bivalent state (Qi et al., 2018).
Figure 2. Diagram of the web-based annotation module function

(A) Data integrated with the web-based annotation module. To locate causal variants and candidate genes or regulatory elements, Triti-Map integrates multi-omics data and provides different levels of analysis, including a collinearity analysis of target regions among Triticeae species, as well as a functional and evolutionary characterization of SNPs, genes, or other sequences related to a target trait.
A candidate gene may be introduced from distant relatives or lost during evolution. To assess these two possibilities, we performed collinearity and evolutionary analyses. Colinear regions corresponding to the candidate region of chromosome 7A were detected in both chromosome 7B and chromosome 7D, both of which contain an \( R \) gene with high sequence homology to \( Pm60 \). No highly homologous gene was detected in the tetraploid A and hexaploid A subgenomes, implying that \( Pm60 \) originated in the common ancestor of diploid wheat but was lost in the A subgenome progenitor before tetraploidization. The corresponding genes in subgenomes B and D underwent divergent evolution and no longer contributed to powdery mildew resistance (Figure 4D). Considered together, these results demonstrate that bulk-segregated ChIP-seq and Triti-Map enable the rapid identification of a candidate causal gene for a specific phenotype that is not present in the reference genome, facilitating functional and evolutionary analyses.

**DISCUSSION**

In this study, we developed Triti-Map, consisting of a suite of scripts and a web-based platform, specifically to address the challenges of Triticeae gene mapping (i.e., large genomes and frequent introgressions), including cases in which the candidate gene is not present in the available reference genome sequences.

First, this pipeline increased the likelihood of identifying agronomic genes absent from the reference genome by integrating information on \textit{de novo} assembled sequences, colinear regions in Triticeae species corresponding to candidate loci, and homologous sequences in public databases. Second, because the ChIP-based strategy could help capture core genomic regions, including genes and regulatory elements (Qi et al., 2018), bulk-segregated ChIP-seq facilitated the detection of non-reference genes and elements and decreased the time and labor required for the analysis and enrichment of the core genome, including both gene body and regulatory regions. Third, in addition to ChIP-seq data, the Triti-Map pipeline accepts other types of DNA- and RNA-seq data.

Plant Communications

and traditional QTL data as the input for locating genes and elucidating their functions. The workflow of this pipeline based on Snakemake is easy to maintain and expand. The ability to add more interval mapping and analysis modules later contributes to the broad utility and flexibility of Triti-Map. Fourth, a comprehensive collection of multi-omics data and a systematic curation of functional and evolutionary information facilitate the functional characterization of sequences. This is useful for precisely and reliably localizing candidate genes and for hypothesis-driven research into specific mechanisms.

There are several publicly available web-based resources for wheat genomic data mining, including resources for visualizing and analyzing BSA results (Zhang et al., 2021) and for identifying collinearity and homology among Triticeae species (Chen et al., 2020). A database of wheat genomic variations and a wheat multi-omics database are also available (Blake et al., 2019; Wang et al., 2020; Chen et al., 2020; Zhang et al., 2021; Ma et al., 2021). Table 2 compares Triti-Map with five wheat genome variation databases and published wheat multi-omics databases. Further mining of the data obtained from bulk-segregated ChIP-seq and Triti-Map using these resources will provide insights into downstream mechanisms.

We anticipate that Triti-Map will improve gene isolation and cloning as well as breeding in Triticeae by decreasing the time and labor required to identify agronomically important genes.

METHODS

Data pre-processing

The following data processing pipeline is included in Triti-Map. Triti-Map accepts ChIP-seq and whole-genome sequencing (WGS) (DNA-seq data) or RNA-seq data as the input. The fastp (0.20.1) program (Chen et al., 2018) is used to remove adapter sequences and low-quality sequencing bases from the raw data. The pre-processed DNA-seq reads are mapped to the reference genome using the default parameters of BWA-mem2 (Vasimuddin et al., 2019). The RNA-seq reads are mapped using the two-pass mode of STAR (Dobin et al., 2013). In brief, the reads are mapped to the reference genome, after which the junction information obtained from the mapping results is used to reconstruct the genome index and perform a second round of mapping.

Variant detection and candidate genomic interval identification

To detect variants from the DNA-seq data, GATK (Van der Auwera et al., 2013) MarkDuplicates is used to remove the duplicated reads resulting from PCR amplification errors during the library preparation step. The RNA-seq data are processed using the pipeline recommended by GATK (https://gatk.broadinstitute.org/). Uniquely mapped reads are extracted, and the variant sites are detected using GATK HaplotypeCaller. To detect mutations, the genome is split by chromosomes for parallel computing. After all of the processes are completed, the data for the variants on each chromosome are merged using GATK MergeVcfs to generate a variant call format (VCF) file containing information on all of the mutation sites.

The variant sites are further filtered according to the quality of the variant sites and genotype information using GATK SelectVariants and GATK VariantFilter. The following combined criteria are used: QualByDepth (QD) >2, FisherStrand (FS) <60, RMSMappingQuality (MQ) >40, StrandOdds-Ratio (SOR) <10, ReadPosRankSum >−8.0, MQRankSum >−12.5, and QUAL >30. To ensure that SNPs are accurately identified, SNPs within a 35-bp sequence are also filtered. Genotype filtering is performed depend-

Plant Communications

Web-based platform construction
A web-based platform was developed using R Shiny, and the front frame was produced using bs4Dash. In this platform, ANNOVAR (Wang et al., 2010) is used to annotate the uploaded mutation information, and GIGGLE (Layer et al., 2018) is used to annotate epigenetic modifications and motifs. The annotations and the results of other analyses are displayed in a formatted table using the R reactive package. The distribution of variant site positions on genes is displayed using the R trackViewer (Ou and Zhu, 2019) package. The distribution of the variant site features, the distribution of chromosomal density, and the results of the collinearity analysis are visualized using echarts4r and plotly.R. The EBI API (Madeira et al., 2019) is used for the functional annotation of sequences and the determination of sequence similarity. The evolutionary tree for homologous genes from different subgenomes is constructed using ggtree (Yu et al., 2017). The genome browser containing data for the apparent modifications in each species is developed based on the JBrowse (Buels et al., 2016) configuration.

Availability of the Triti-Map package and web-based interface
The Triti-Map package was developed using Snakemake (Koster and Rahmann, 2012) and Conda. The package and manual are available online (https://github.com/fei0810/Triti-Map). Triti-Map can be installed from Bioconda (Gruning et al., 2019) and Docker. The web-based Triti-Map interface is also accessible (http://bioinfo.cemps.ac.cn/tritimap).

Sample and sequencing data processing for a case study involving the detection of a disease-resistance gene
The powdery mildew-resistant common wheat cultivar 3D249 is an F2 wheat-WEW (wild emmer wheat) introgression line developed by Professor Tsimin Yang of China Agricultural University, Beijing (pedigree: Jingshuang 27/Yanda, 1817/WE18/3/Wenmai 4). The common wheat cultivar Xuezao is highly sensitive to Blumeria graminis f. sp. graminis (Bgt) #E09. Two-week-old seedlings of 30 F3 generation homozygous resistant and susceptible materials derived from a Xuezao × 3D249 hybridization were pooled to construct resistant and susceptible DNA bulks for a ChiP-seq analysis. The ChiP experiments involved antibodies specific for H3K27me3 (Upstate, cat. no. 07-449), H3K4me3 (Abcam, cat. no. Ab8580), and H3K36me3 (Abcam, cat. no. Ab9050). The Illumina HiSeq 2500 system was used for sequencing (150-bp paired-end reads) (Beijing Nuohuo Company).

Data access
The package and manual are available online (https://github.com/fei0810/Triti-Map). Triti-Map can be installed from Bioconda and Docker. The web-based Triti-Map interface is also accessible (http://bioinfo.cemps.ac.cn/tritimap).

The ChiP-seq data have been deposited in the Sequence Read Archive (SRA) and assigned the identifier accession PRJNA725543 (https://www.ncbi.nlm.nih.gov/bioproject/PRJNA725543).
