Theory of a Scanning Tunneling Microscope with a
Two-Protrusion Tip

Abstract

We consider a scanning tunneling microscope (STM) such that tunneling occurs through two atomically sharp protrusions on its tip. When the two protrusions are separated by at least several atomic spacings, the differential conductance of this STM depends on the electronic transport in the sample between the protrusions. Such two-protrusion tips commonly occur during STM tip preparation. We explore possible applications to probing dynamical impurity potentials on a metallic surface and local transport in an anisotropic superconductor.
Scanning tunneling microscopy (STM) enables the characterization of materials on the atomic scale through measurements of the local density of states (LDOS). Recently, in a series of STM experiments on the Cu (111) surface, the local transport properties of electrons in a Shockley surface state were probed through their influence on the LDOS around an Fe impurity [1]. A similar experiment has been proposed for measuring the transport properties of a high-temperature superconductor [2]. These experiments detect the reflection from the impurity of electrons injected by the STM. The spatial resolution of these experiments is sub-Angstrom. Properties which might be determined from these types of measurements, but could not be probed by an STM measurement on the homogeneous sample, include the angularly-resolved dispersion relations and mean free path, as well as the density of states as a function of energy and momentum. In the Cu experiments the dispersion relation was measured, no evidence for density-of-states anisotropy with angle was found, and the mean free path was too large to detect.

A stronger signal would result from an independent method of injecting electrons at a site (by another contact) and detecting them elsewhere with an STM. The possibilities for this have been explored in recent work [3,4] and will be referred to as the two-contact experiment. A related technique, applicable to transport on a longer length scale (µm), uses a laser to create nonequilibrium quasiparticles and a point contact to detect them [5].

The STM is also sensitive to the spectroscopic properties of impurities [6,7]. However an STM averages over the fluctuating part of an impurity potential, such as that of a free orbital moment, making it difficult to observe. Such free moments are of great interest in part because their interaction with conduction electrons may produce a Kondo resonance.

We suggest in this Letter an experiment which should provide detailed angular information about fluctuating impurity potentials and probe transport on a homogeneous sample. The apparatus, shown schematically in Figure 1, would consist of a spatially-extended STM tip with two protrusions each ending in a single atom. Although the case of STM tips with tunneling at more than one place has been considered before [8], that work was concerned with tips ending in clusters with substantial tunneling through more than one atom. The
images obtained from these STM tips tended to be blurry and less useful than those from single-atom-terminated contacts. Here we propose a tip with two atomically-sharp protrusions, and will demonstrate that new information is obtainable when these protrusions are separated by more than 10Å. In contrast to the difficulties associated with arranging two independent contacts in close proximity, two-protrusion tips are often created by chance during tip preparation, with tip separations up to 1000Å. The interference between the two protrusions influences tunneling conductances at a lower order in the tunneling matrix elements than the two-contact experiment. The two-protrusion experiment, therefore, should be easier to construct and have greater signal than the two-contact experiment.

For separations of 10Å−100Å a two-protrusion tip would be useful for probing the angular structure of a free moment. The differential conductivity depends on the angle-resolved amplitude for electrons to scatter from the impurity. A measurement with a single-protrusion STM tip merely measures backscattering. For an impurity state fixed relative to the lattice orientation by the crystal field, backscattering is sufficient to determine the impurity’s angular structure; therefore the single-protrusion measurement provides as much information as the two-protrusion one. However, for identifying the angular structure of a free moment, the two-protrusion tip is superior to the single-protrusion tip. A two-contact experiment could in principle measure this angular structure as well, but positioning two tips within 100Å of each other would be extremely difficult.

On a homogeneous sample the transport quantities of interest would determine the desired separation of protrusions on the STM tip. Measurements of quantities with long length scales (100Å−1000Å) such as mean free paths, transitions from ballistic to diffusive propagation, low-\(T_c\) superconductors’ coherence lengths, charge-density-wave correlation lengths, and angularly anisotropic density-of-states effects would most benefit from the increased signal of the two-protrusion configuration relative to the two-contact configuration. It is also at these distances that the overlapping interference of other impurities on a surface would complicate a measurement performed with a single-protrusion STM around an impurity. However, for electronic quantities with short length scales, such as Fermi wavelengths, the
single-protrusion STM would likely perform the best of the three.

The tunneling Hamiltonian

\[ H_T = \int d\mathbf{x} d\mathbf{r} \left[ T(\mathbf{x}, \mathbf{r}) \psi^\dagger(\mathbf{x}) \phi(\mathbf{r}) + \text{H.c.} \right], \]

where \( \psi(\mathbf{x}) \) is the field annihilation operator for an electron at position \( \mathbf{x} \) in the STM tip, and \( \phi(\mathbf{r}) \) is the field annihilation operator for an electron at position \( \mathbf{r} \) in the sample. The electron spin is treated implicitly to simplify the notation. The differential conductance of the STM at \( T = 0K \),

\[ \frac{dI}{dV} = \frac{2e^2}{h} \int d\mathbf{x} d\mathbf{r} d\mathbf{x}' d\mathbf{r}' T(\mathbf{x}, \mathbf{r}) T^*(\mathbf{x}', \mathbf{r}') \text{Im} g(\mathbf{x}, \mathbf{x}'; 0) \text{Im} G(\mathbf{r}', \mathbf{r}; eV), \]

where \( G \) is the Green function in the sample and \( g \) is the Green function in the STM tip.

Typically the transfer function \( T(\mathbf{x}, \mathbf{r}) \) is taken to be localized near a point in the sample and the tip: \( T(\mathbf{x}, \mathbf{r}) = W v(\mathbf{x} - \mathbf{x}_o) v'(\mathbf{r} - \mathbf{r}_o) \), where the integrals of \( |v|^2 \) and \( |v'|^2 \) are unity. With \( v' \) a highly-localized function the differential conductance is proportional to

\[ \text{Im} \tilde{G}(\mathbf{r}_o, \mathbf{r}_o; eV) = \text{Im} \int d\mathbf{r} d\mathbf{r}' v'(\mathbf{r} - \mathbf{r}_o)^v(\mathbf{r}' - \mathbf{r}_o) G(\mathbf{r}, \mathbf{r}' ; eV) \sim \text{Im} G(\mathbf{r}_o, \mathbf{r}_o; eV). \]

When \( v \) is also very localized the proportionality constant is \( e^2 |W|^2 N(0)/h \), where \( N(0) \) is the density of states in the tip at the Fermi energy. The expression \( dI/dV = e^2 |W|^2 N(0) \text{Im} G(\mathbf{r}_o, \mathbf{r}_o; eV)/h \) is a common starting point for STM theory.

We model the effect of a single impurity resonance by the Hamiltonian term

\[ H_I = \int d\mathbf{r} \left[ A(\mathbf{r}) \phi(\mathbf{r})^\dagger \chi + A^*(\mathbf{r}) \phi(\mathbf{r}) \chi^\dagger \right] \]

where \( \chi \) is the annihilation operator for an electron in the localized state. For a simple model, \( A(\mathbf{r}) \propto \Psi(\mathbf{r}) \), the (normalized) wavefunction of the impurity state. The Green function is then

\[ G(\mathbf{r}_1, \mathbf{r}_2; eV) = \int d\mathbf{r}' G(\mathbf{r}_1, \mathbf{r}; eV) \frac{A(\mathbf{r}) A^*(\mathbf{r}')} {eV - E_I + i\Gamma} G(\mathbf{r}', \mathbf{r}_2; eV) \]

\[ = \int d\mathbf{r}' G(\mathbf{r}_1, \mathbf{r}; eV) \frac{\Psi(\mathbf{r}) \Psi^*(\mathbf{r}')} {\pi N_s} G(\mathbf{r}', \mathbf{r}_2; eV), \quad eV = E_I \]
where $E_I$ and $\Gamma$ are the energy and linewidth of the impurity state and $N_s$ is the density of states of the sample at $E_I$. We assume there is no other influence on $\Gamma$ besides hopping to the extended states. For a $d$-state, $\Psi(r) = (2/\xi \sqrt{\pi})e^{-r/\xi} \cos(2\theta r)$, where $\xi$ is the range of the state. For a fixed $d$-state, $\theta_r$ is measured relative to a crystallographic axis. Figure 2 shows the single-protrusion differential conductance in the vicinity of a fixed impurity $d$-state with $\xi = 2k_V^{-1}$ ($k_V$ is the wavenumber of the electronic state with energy $eV$). It shows clear four-fold symmetry. If the crystal field splitting of the impurity levels is larger than the temperature and $\Gamma$, the STM can separately probe each non-degenerate level by adjusting the voltage.

The two-protrusion experiment becomes more useful than the single-protrusion experiment when the impurity of interest has a free moment. Then the $dI/dV$ must be averaged over orientations of $\theta_r$ in Eq. (3) (and Fig. 2). The two-protrusion transfer function, however, contains contributions from both tunneling sites below the protrusions: $T(x, x') = \sum_i W_i v_i(x - x_i) v_i'(x - x_i)$, where for simplicity we consider $v, v'$, and $W$ to be independent of $i$. The STM current for this system is

$$\frac{dI}{dV} = \frac{2e^2 |W|^2}{\hbar} \sum_{i,j = 1}^{2} \text{Im} \tilde{g}(x_i, x_j; 0) \text{Im} \tilde{G}(r_j, r_i; eV).$$

The $i = j$ terms describe direct tunneling through the two protrusions, but the $i \neq j$ terms are interference terms between the two protrusions. We approximate $\text{Im} \tilde{g}(x, x'; 0)$ by $N(0) \exp(-|x - x'|/\ell_I)$ where $\ell_I$ is the inelastic mean free path [12]. A favorable tip material would have a large $N(0)$ and a long $\ell_I$. Figure 3 shows two-protrusion measurements of a $d$-orbital which is free to move in the plane of the surface. The $dI/dV$ is plotted as a function of distance from the impurity $r$ (same for both protrusions) and angle $\theta$ between the two tips. A single-protrusion measurement corresponds to $\theta = 0$. The four-fold structure of the $d$-orbital is clearly visible in Figure 3, which should be thought of as a compilation of results which must come from many different tips, since for each tip the distance between protrusions is fixed.

A measurement with a particular tip, with separation $7.5k_V^{-1}$, is shown in Figure 4. The
differential conductance through the two protrusions at $\mathbf{r}_1 = (x, 3.75)$ and $\mathbf{r}_2 = (x, -3.75)$ is compared to the differential conductance of a single protrusion located at $\mathbf{r}_1$ with tunneling matrix element $2W$. The geometry is shown in Figure 1. The differential conductances for $x = 0$ ($\theta = \pi$) are identical and at large $|x|$ (where $\theta$ is small) the two are very similar. The most prominent difference is the absence in the two-protrusion $dI/dV$ of a peak near $x = \pm 3.75$. Since $\theta = \pi/2$ for $x = 3.75$, the direct $i = j$ terms are almost fully cancelled by the $i \neq j$ terms in Eq. (7). We emphasize there is no need to rotate the tip assembly to perform this measurement. If the impurity moment is free, for any tip orientation the geometry of Figure 1 can be arranged solely by translation of the tip. The orientation and protrusion separation of the tip can be identified by analyzing the double image from an impurity or a step edge.

We now apply Eq. (7) to transport between the two protrusions through a $d_{x^2-y^2}$-gapped superconductor. A $d_{x^2-y^2}$ gap has been proposed [13] for high-$T_c$ superconductors, including Bi$_2$Sr$_2$CaCu$_2$O$_8$. A very clean surface can be prepared on Bi$_2$Sr$_2$CaCu$_2$O$_8$ so that transport is ballistic, and the mean-free path is $10^3 - 10^4$ Å [14] at 4.2K. Bi$_2$Sr$_2$CaCu$_2$O$_8$ is a layered structure with weakly-coupled planes, so we calculate the Green’s functions for a $d_{x^2-y^2}$-gapped superconductor with a cylindrical Fermi surface [2]. Figure 5 shows the position-dependent differential conductance as a function of $x$ and $y$ for the $d_{x^2-y^2}$ gap $\Delta_k = \Delta_{max} \cos(2\phi_k)$. $\phi_k$ is the angle that the momentum $\mathbf{k}$ makes with the crystallographic $a$-axis. The voltage bias is set well below the gap maximum ($eV = 0.1\Delta_{max}$) so that the quasiparticles are only able to propagate in the directions where $\Delta_k$ has nodes.

In a heuristic sense, gap anisotropy produces an angularly-dependent density of states, which can be qualitatively different at different energies. For a $d_{x^2-y^2}$ gap, at voltages much less than the gap quasiparticles can only travel in the real-space directions roughly parallel to node momenta, yielding “channels” of conductance [3]. At voltages slightly higher than the gap maximum there are more states for momenta near the gap maximum, so the channels would appear rotated by 45°. Measurements of gap anisotropy, particularly from angle-resolved photoemission [15], are of great current interest for distinguishing among
various theories of high-temperature superconductivity. Tunneling experiments have an energy resolution better than an meV, far superior to angle-resolved photoemission. Again it is not necessary to rotate the tip assembly since regions of the sample with different orientations (separated by grain boundaries) could be measured instead.

The signal in this two-protrusion transport experiment is greater than the two-contact or impurity configurations because the interference terms in Eq. (7) are first-order (proportional to $|W|^2$). The two-contact experiment relies on a second-order process, proportional to $|W|^4$. The impurity transport experiment [2] relies on a process which is first-order in tunneling, $|W|^2$, and impurity-scattering $|U|^2$ (the $U$ is the potential strength), and thus overall is second order ($|W|^2|U|^2$).

The primary goal of this Letter has been to offer an example of how a two-protrusion STM can explore the characteristics of fluctuating impurity potentials and the local transport properties of a homogeneous sample. A two-protrusion $dI/dV$ indicates the angular symmetry of an impurity state in a similar way to how a differential cross-section of a particle-atom collision indicates the angular symmetry of an atomic state. Measuring gap anisotropy is merely one possible application of the ability to directly and in detail probe small-scale electronic transport in a homogeneous sample.
