ABSTRACT

We measure the weak-lensing masses and galaxy distributions of four massive galaxy clusters observed during the Science Verification phase of the Dark Energy Survey. This pathfinder study is meant to 1) validate the DECam imager for the task of measuring weak-lensing shapes, and 2) utilize DECam’s large field of view to map out the clusters and their environments over 90 arcmin. We conduct a series of rigorous tests on astrometry, photometry, image quality, PSF modeling, and shear measurement accuracy to single out flaws in the data and also to identify the optimal data processing steps and parameters. We find Science Verification data from DECam to be suitable for the lensing analysis described in this paper. The PSF is generally well-behaved, but the modeling is rendered difficult by a flux-dependent PSF width and ellipticity. We employ photometric redshifts to distinguish between foreground and background galaxies, and a red-sequence cluster finder to provide cluster richness estimates and cluster-galaxy distributions. By fitting NFW profiles to the clusters in this study, we determine weak-lensing masses that are in agreement with previous work. For Abell 3261, we provide the first estimates of redshift, weak-lensing mass, and richness. In addition, the cluster-galaxy distributions indicate the presence of filamentary structures attached to 1E 0657-56 and RXC J2248.7-4431, stretching out as far as 1 degree (approximately 20 Mpc), showcasing the potential of DECam and DES for detailed studies of degree-scale features on the sky.

1 INTRODUCTION

The Dark Energy Survey (DES) comprises an optical to near-infrared survey over 5,000 deg² of the South Galactic Cap to ~24th magnitude in the SDSS $grizY$ bands and a time-domain $griz$ survey over 30 deg² with a cadence of approximately six days. These inter-leaved surveys are being carried out over 525 nights in the course of five years using the 570-megapixel imager DECam (Flaugher et al. 2012; Diehl 2012) mounted at the prime focus of the Blanco 4m telescope at NOAO’s Cerro Tololo Inter-American Observatory. DECam was commissioned in September and October of 2012, followed by an extended testing and survey commissioning period known as DES Science Verification (SV, November 2012 – February 2013). With this new instrument, DES will go beyond the reach of SDSS by virtue of telescope aperture, median seeing, and CCD sensitivity, particularly towards the infrared part of the spectrum. Consequently, the galaxy redshift distribution is expected to have a median $z \approx 0.7$ and a significant tail beyond $z \approx 1$, which enables DES to detect clusters at high redshift ($z \approx 1$) and to use source galaxies for a rigorous lensing analysis of clusters beyond $z \approx 0.5$. DES will also exceed deep and medium deep weak lensing surveys (CFHTLS, RCS2, DLS) by up to an order of magnitude in area. More details about the survey can be found in The Dark Energy Survey Collaboration (2005) and at http://www.darkenergysurvey.org.

The very wide field of view of DECam of slightly more than 3 deg² allows us to capture the environment of even the most massive galaxy clusters with a single pointing. In this paper we will show results on four fields containing clusters with masses of approximately $1 - 2 \times 10^{15} M_\odot$ and redshifts from $z = 0.22$ to $z = 0.40$. They have been chosen to demonstrate the capabilities of DECam imaging for cluster and lensing analyses and provide an outlook of the utility of the entire DES to map out a good fraction of the sky to redshifts of about 1.

The goals of this pathfinder study are twofold. First, to validate the data quality delivered by DECam for the purpose of galaxy cluster and lensing studies. We focus our attention on four fields imaged during the SV period in $grizY$ filters with integration times characteristic of the DES to study the relevant elements of photometry and image quality. We inspect our ability to model the point spread function (PSF) and to account for possible systematic contaminants of photometry and lensing analyses. We emphasize that this is not a comprehensive study of the DES pipelines for photometry or lensing; those studies will be presented elsewhere.

Second, we want to utilize the large field of view of DECam to map the environments of these clusters over 90 arcmin, probing cluster-centric distances between 10 and 15 Mpc at the respective cluster redshifts. We select background galaxies according to their cluster-centric distances between 10 and 15 Mpc at the respective cluster redshifts. We select background galaxies according to their cluster-centric distances between 10 and 15 Mpc at the respective cluster redshifts. We select background galaxies according to their cluster-centric distances between 10 and 15 Mpc at the respective cluster redshifts. We select background galaxies according to their cluster-centric distances between 10 and 15 Mpc at the respective cluster redshifts. We select background galaxies according to their cluster-centric distances between 10 and 15 Mpc at the respective cluster redshifts.

Section 2 contains the details of the observations and data reduction pipeline used in this study. Section 3 describes the photometric calibration (Section 3.1), the redMaPPer technique for identifying red-sequence galaxies (Section 3.2), the photometric redshift methodology (Section 3.3), and the background galaxy selection procedure (Section 3.4). Section 4 describes the lensing analysis, detailing PSF estimation (Section 4.1), shape measurements with m3shape (Section 4.2), and the combination of measurements in three bands into a single shape catalog (Section 4.3). We perform additional tests of the recovered cluster shears in Section 4.4 and present the NFW-profile fits and lensing mass estimates in Section 5.1 and the mass-richness relation in Section 5.2. We show mass and cluster galaxy maps in Section 6 and indications for the presence of filamentary structures in two of the investigated fields (Section 6.2). We summarize our findings in Section 7.

For the entire paper we adopt a flat $\Lambda$CDM cosmological model with $\Omega_m = 0.3$ and $H_0 = 100 h$ km/s/Mpc, where $h = 0.7$.

| Cluster name     | Label | RA [deg] | Dec [deg] | $z$ |
|------------------|-------|----------|-----------|-----|

| SC SOS J233227-535827 | SPTW1 | 353.11146 | -53.97441 | 0.402 |
| Abell 3261       | Abell3261 | 67.31375 | -60.32555 | —   |

1 In the course of this program, we also observed ACT-CL J0102-4915 (dubbed El Gordo, Menanteau et al. 2010b), but the images are rather shallow for a dedicated weak-lensing analysis of this cluster at $z = 0.87$. We therefore omit the cluster in this work.

2 One key decision made by OtsTac is to observe in the $r, i, z$ bands only if the seeing in the proposed band is better than 1.7′′, taking into account the chromatic and airmass dependence.
2.1 Observational conditions

The conditions during the observations were generally stable and mostly photometric. During the November runs, the moon illumination was bright enough to significantly reduce the depth in $g$ and $r$, triggering re-observations during dark conditions on December 7. The seeing in these nights varied between $0.8$ and $1.0''$, and varied only slowly with time during the same night, indicating that the PSF is dominated by the optics rather than the atmosphere. If observations spanned multiple nights, non-trivial variations occurred, which render the PSF modeling more challenging. The observations from November exhibit a predominant elongation in the right ascension due to telescope tracking oscillations. Because of mechanical improvements of the telescope between these first sets of exposures and the re-observations on December 7 and later during the SV period, the latter ones show smaller overall ellipticity and can be well described by the typical optical aberrations of a wide-field imager. An overview of average seeing conditions for all data in question is given in Table 2.

Table 2. Average PSF width (seeing) and ellipticity for each filter in each of the four fields, with re-observations indicated by a running number. Observations marked with † were completed in the following night; those marked with‡ were taken under OnsTuc control during survey-mode operations between December 2012 and January 2013. Seeing is given in terms of the FWHM in arcsec, the ellipticity in terms of shears, not polarizations. The last column ‘Shapes’ denotes whether the coadd image was suitable for a weak-lensing shape analysis (see Section 4.1.2 for details on the selection).

Figure 1. Galaxy number density $n_{gal}$ in bins of SExtractor’s magnitude MAG_AUTO in the $i$-band. From top to bottom: detected sources (black); after cleaning the catalog (blue); galaxies with successful shape measurements (yellow); galaxies considered in the lensed background sample (red). See Section 4.3 for details on the selections. The numbers are unweighted, averaged over all four fields.

2.2 Coadd images and catalogs

Our treatment of the data begins with single-epoch images that have been processed through the DES Data Management (DESDM) pipeline (Mohr et al. 2012; Desai et al. 2012). Because a significant portion of our observations was taken early in the SV program, we first visually inspected our images for adequate data quality and rejected problematic exposures, e.g. those affected by occasional guiding failures. We excluded symptomatic frames, characterized by elongated, distorted stellar profiles. In a few instances we also rejected exposures showing significant levels of scattered light across the focal plane.

The DESDM pipeline already implements several standard detrending corrections for the raw data. The overscan is subtracted and a crosstalk matrix removes effects that bright stars induce across the detector. Bias frames and dome flats are averaged over several nights and then applied to the data. Included in the DESDM reductions are fringe and pupil-ghost corrections as well as the photometric calibration, which we detail in Section 3.1.

Astrometric solutions are computed by DESDM using scamp (Bertin 2006), matching absolute stellar positions in each exposure separately to the UCAC4 reference catalog (Zacharias et al. 2012). While we do not require precise absolute astrometry, the relative astrometry between individual exposures is critical for accurate shape measurements. We therefore re-run scamp, simultaneously matching all filters and exposures to each other as well as to the much sparser reference catalog. Typical errors after this step are 5 mas shifts between bands and 20 mas scatter within a band, improving the single-epoch solutions by factors of $\sim 3$.

We then coadd the single-epoch images of each $g, r, i, z, Y$ filter band separately. Additionally, we combine the bands considered for shape measurement into a multi-band $rizY$ coadd for use as a source detection image of increased depth and redshift coverage. Coaddition is implemented with SWarp (Bertin et al. 2002), using a clipped mean algorithm we have added to the software (Gruen et al. 2014a), which rejects pixels that are outliers at the $4\sigma$ level. In contrast to median coadds, this approach successfully rejects cosmic-ray hits without sacrificing image fidelity and statistical optimality or altering the PSF shape, critical for weak lensing studies.

$^3$ to the degree we could determine from our observations, which comprise the Bullet cluster field that exhibits a strongly enhanced stellar density due to its low galactic latitude. However, dedicated studies on star clusters were not performed.

$^4$ In contrast to median coadds, this approach successfully rejects cosmic-ray hits without sacrificing image fidelity and statistical optimality or altering the PSF shape, critical for weak lensing studies.
ing coaddition, appropriate flux scalings are applied to each image using the zeropoints calculated by the DESDM photometric calibrations.

We run SExtractor (Bertin & Arnouts 1996) in dual-image mode: we provide the riz coadd for detection of sources and assignment of pixels to detections, afterwards the photometric measurements are made from the single-band values in these pixels. The detection threshold is set to 1.5\(\sigma\) above noise in at least six contiguous pixels. The magnitude distribution of detected sources can be seen in Figure 1.

Finally, we define a field mask to restrict the analysis to full-depth areas, excluding the edges of each pointed field (RXJ, Bullet, and SPTW1). We decided on a square shape with a side-length of 1.5 deg with trimmed corners (shown in the left two panels of Figure 3), the center of which was adjusted so as to maximize the number of total detections.

### 3 PHOTOMETRY AND GALAXY SAMPLE SELECTION

In this work, the major role of photometry is to separate galaxies by color and to assign photometric redshifts to them for proper calculation of cosmological distances and lensing weight factors (Section 4.3). We will therefore only introduce the general photometric approach, focusing on aspects most relevant for this study and discussing the accuracy with which we can perform these photometric tasks, and refer the reader to forthcoming publications for details.

#### 3.1 Photometric calibration

Each individual exposure is first processed to bring all pixels of the array onto a common photometric scale. Details are given in Tucker et al. (2007), so we only summarize the main aspects here. After bias subtraction, the images are divided by a dome flat. The dome flat is known, however, to have variations due to stray light and to changes in the effective pixel area. To reduce the impact of these variations on the object photometry we divide the images by dome flat (Gorski et al. 2005), which provides a correction for 512 \(\times\) 512 pixel regions on each CCD (32 regions per CCD) that minimizes the dependence of the stellar photometry on the DECam focal plane position.

Exposures taken on clear nights are brought to a common absolute magnitude scale by using a zeropoint that is a linear function of airmass, with slope and offset fit to observations of SDSS photometric standard fields taken at the beginning and end of the night. At least one photometric exposure is required for each filter in each field. We use these observations to create a local set of standard stars, for each field, by averaging over all overlapping objects. We then refit all CCD zeropoints from both photometric and non-photometric conditions by allowing each DECam CCD on each exposure to have its own zeropoint. Zeropoints are adjusted to minimize the difference in magnitude between observations of common objects in different exposures and observations of the aforementioned local standards. This method typically gives an RMS accuracy of \(\sim 1\%\) and has been validated by comparing measurements of the stellar locus in color-color space, as described below.

Stellar locus regression (SLR) has proven to be a useful complementary photometric calibration method to standard star observations, and relies upon the approximate universality of the intrinsic colors of Milky Way halo stars as a population (e.g., High et al. 2009). In the SLR approach, zeropoints for each filter are adjusted until the foreground stars lie along the expected color-color locus.

Since the great majority of stars detected in our DECam images are located beyond the Galactic dust sheet, the SLR is sensitive to the combined effects of atmospheric and interstellar extinction.

Our SLR implementation employs the publicly available Big MACS\(^5\) code developed by Kelly et al. (2014). The reference stellar locus is synthetically generated using the Pickles (1998) stellar spectroscopic library spliced with SDSS spectra (as described in Kelly et al. 2014) and convolved with the DECam total system transmission functions. Stars in the cluster fields are selected by requiring SExtractor’s stellarity parameter CLASS_STAR > 0.95 in both the r and i band, which provides adequate star-galaxy separation for high signal-to-noise objects. Accordingly, we also require magnitude uncertainties of \(< 0.05\) (< 0.1) in the r (i) bands. In order to evaluate the photometric calibration across each cluster field, stars are binned into HEALPix\(^6\) (Gorski et al. 2005) pixels with a resolution of \(\sim 14\) arcmin (NSIDE=256).\(^7\) We then allow the zeropoints of the DECam griz filters to float independently in each spatial pixel during the fits and use the J-band magnitudes of matched 2MASS stars for absolute calibration. The zeropoint shifts fitted via SLR are typically \(\lesssim 0.05\) mag, with an associated statistical precision of \(\sim 0.02\) mag estimated via bootstrapping of the stellar sample. The exception is the Bullet cluster field, where the median g-band zeropoint shift is \(\sim 0.2\) mag, consistent with interstellar extinction expected in this low-Galactic-latitude field from the dust maps produced by Schlegel et al. (1998).

#### 3.2 Cluster member selection

Our study uses the methodology from the red-sequence matched filter probabilistic percolation (“redMaPPer”) algorithm (Rykoff et al. 2014), based on the optimized richness estimator \(\lambda\) (Rykoff et al. 2012), redMaPPer is a photometric cluster finder that identifies galaxy clusters as overdensities of red-sequence galaxies, and has been shown to have excellent performance in phot-z determination, purity, and completeness for wide-field photometric surveys (Rozo & Rykoff 2014). The algorithm is divided into two stages: the first is a calibration stage where the red-sequence model is derived directly from the data, and the second is the cluster-finding stage. These two stages are iterated several times before a final cluster-finding run is performed.

In the calibration phase, redMaPPer empirically calibrates the color distribution (mean and scatter) of red-sequence galaxies as a function of redshift and magnitude. For the red-sequence calibration, 356 spectroscopically confirmed BCGs in the 241-deg\(^2\) griz DES SV-A1 galaxy catalog (Rykoff et al., in prep.) were used. The spectroscopic redshifts were taken from SDSS DR10 (Ahn et al. 2014), SPT clusters (High et al. 2010), and as part of the OzDES program (Lidman et al., in prep). These galaxies are used as “seeds” to look for significant overdensities of nearby galaxies with similar color as the seed galaxy (\(g-r, r-i,\) or \(i-z\) depending on the redshift, as determined from MAG\_DETMODEL\(^8\) magnitudes). The resulting set of cluster galaxies is used to fit a full red-sequence model including zero point, tilt, and scatter. This scatter is characterized by a full

---

\(^5\) http://code.google.com/p/big-macs-calibrate/

\(^6\) http://healpix.sourceforge.net/

\(^7\) The choice of 14 arcmin constitutes a compromise between increasing angular resolution and maintaining a sufficient number of stars in each pixel such that statistical uncertainties are \(\sim 0.02\) magnitudes.

\(^8\) In SExtractor’s dual-image mode, MAG\_DETMODEL measures the flux in each filter by adopting a model fit to the object in the detection image, in our case the riz coadd.
covariance matrix among all colors (see Rykoff et al. 2014 for details). The red-sequence model is calibrated down to a luminosity threshold of 0.2$L$, at the cluster redshift, which was determined to be the optimal depth for cluster richness estimation (Rykoff et al. 2012). In this way we leverage the bright spectroscopic sample to obtain a model of the red sequence that extends to faint magnitudes.

Given the red-sequence model and the corrected magnitudes, the cluster-finding proceeds as follows. First, we consider all photometric galaxies as candidate cluster centers. The red-sequence model is used to calculate a photometric redshift for each galaxy, and evaluate the goodness of fit of our red-sequence template. Galaxies that are not a reasonable fit to the model at any redshift are immediately discarded. For the remaining galaxies, we use this initial redshift guess to evaluate the richness $\lambda$ and the total cluster likelihood. When at least 3 red sequence galaxies (brighter than 0.2$L$, within a scale radius $r_s$) are detected, we re-estimate the cluster redshift by performing a simultaneous fit of all the high-probability cluster members to the red-sequence model. This procedure is iterated until convergence is achieved between member selection and cluster photometric redshift, denoted $z_\ell$. The resulting list of candidate cluster centers is then rank-ordered according to likelihood, and membership probabilities are used to mask out member galaxies in the final percolation step. All richness values are corrected for variations in the local depth of the DES imaging (Rykoff et al., in prep.), however, the DES imaging is deep enough that this has a negligible effect at the redshifts of the clusters considered in this paper. We have shown that for $\lambda > 20$ the cluster purity and completeness are $> 95\%$ (Rykoff et al. 2014; Rozo & Rykoff 2014). In addition, even for $\lambda > 5$ the photo-$z$ performance is very good, with a scatter $\sigma_z < 0.015$ for SV-A1 data (Rykoff et al., in prep).

3.3 Photometric redshifts

We compute photometric redshifts (photo-$z$’s) using the artificial neural network method that was applied to the Sloan Digital Sky Survey Data Release 6 (DR6) sample, as described in detail by Oyazui et al. (2008a). In brief, we use a neural network configuration with 10 input nodes, consisting of 5 griY MAG AUTO magnitudes and 5 griY MAG DETMODEL magnitudes, followed by 3 hidden layers with 15 nodes per layer. The neural network was trained using a set of about 12,000 galaxies with DES main-survey depth photometry and high-confidence spectroscopic redshifts.

The accompanying photo-$z$ errors are computed using the empirical “nearest neighbor error” (NNE) technique, described in detail by Oyazui et al. (2008b). The NNE method estimates the photo-$z$ error for each galaxy empirically, based on the photo-$z$’s and redshifts of the galaxy’s 100 nearest neighbors in the spectroscopic validation sample, where neighbor distance is defined using a simple flat metric in the space consisting of the 10 input magnitudes noted above. Specifically, the NNE photo-$z$ error $\Delta z_{\text{phot}}$ is defined so that it corresponds to 68% of the $[z_{\text{phot}} - z_{\text{spec}}]$ distribution of the nearest neighbors. In DES comparison tests by Sánchez et al. (2014), where the method we employ here is called DESCMD, it shows a marginal bias ($\Delta z$) = $-0.005 \pm 0.003$, a scatter of $\sigma_{\delta z} = 0.094 \pm 0.002$, and a 3-$\sigma$ outlier rate of 0.018 ± 0.003. All of these metrics indicate that the photo-$z$ accuracy is easily sufficient for the purpose of this work. For further details, we refer the reader to Sánchez et al. (2014).

The photo-$z$s also serve us to estimate

$$\Sigma_{\text{crit}} = \frac{c^2}{4\pi G^2 D_l D_m}$$

(1)

which will be used below to relate the gravitational shear $\gamma$ to the surface density contrast of the cluster lens

$$\Delta \Sigma = \Sigma_{\text{crit}} \gamma.$$ (2)

In Equation 1, $D_l$ denotes angular diameter distance: to a source at photometric redshift $z_{\text{phot}}$, to the lens at the spectroscopic redshift $z_l$ (cf. Table 1; for Abell 3261, we adopt the redMaPPer estimate from Table 4), and between lens and source.

3.4 Background galaxy selection

We select background galaxies according to their photometric redshifts $z_{\text{phot}}$ by requiring that

$$z_{\text{phot}} > z_l + 0.2.$$ (3)

This seemingly straightforward selection is very effective at selecting a sample of galaxies that are behind the cluster, but due to the finite accuracy of the photo-$z$s it is not perfect. Two main limitations need to be addressed and are discussed below.

3.4.1 Cluster-member contamination

Even though we reject all redMaPPer-detected galaxies in groups close to $z_l$ from the background sample, we find that the number density of nominally background galaxies, for which we have both a photo-$z$ and a shape estimate (see Section 4.3 for details), rises strongly towards the cluster centers (cf. Figure 2). The rise is caused by cluster member galaxies, for which neither redMaPPer nor the photo-$z$s are complete or accurate enough to put them at the cluster redshift. As expected, the chance of such galaxies getting up-scattered to a particular redshift drops with increasing separation between $z_l$ and $z_{\text{phot}}$.

Like Applegate et al. (2014), we correct for this effect by fitting an exponential model to the galactic number density as a function of cluster-centric distance $r$,

$$n_{\text{occ}}(r) = n_0 \left[1 + \delta n_{\text{c}} \exp \left(\frac{r}{\alpha_{\text{c}}}ight)\right],$$ (4)

where $\delta n_{\text{c}}$, $r_c$, and $\alpha_{\text{c}}$ are free parameters and allowed to differ for each cluster $C$ and each photo-$z$ slice $Z$. The slices are chosen to have a roughly constant and sufficient number of galaxies to allow a successful fit. The resulting fits are shown as solid lines in Figure 2. If we assume all of these contaminating galaxies to be randomly oriented, their effect is to reduce the perceived lensing effect of the background sample proportional to the contamination fraction. Following Blazek et al. (2012), we can therefore absorb the correction term into

$$\Sigma_{\text{c},\text{e},\text{L},Z} = \Sigma_{\text{crit}} \left[1 + \delta n_{\text{c}} \exp \left(\frac{r}{\alpha_{\text{c}}}ight)\right].$$ (5)

Note that $\Sigma_{\text{crit}}$ still depends on the actual (central) value $z_{\text{phot}}$ of each

9 If any form of additional weighting is employed (as we will do with Equation 15 later on), $n_0$ needs to refer to the weighted number density.

10 Intrinsic alignments, in particular in combination with photo-$z$ errors, could introduce non-random contributions to the lensing signal, but their strengths have been found to be insignificant for the work presented here (e.g. Chisari et al. 2014; Sifón et al. 2014).
source, but the correction term is necessarily averaged over photo-z slices of \( \sim 0.2 \) width. Because the contamination fraction quickly rises when \( z_{\text{phot}} \to z_c \), we expect that this best-effort correction is not entirely accurate, specifically for the lowest photo-z slices.

As detailed in Applegate et al. (2014), to obtain a meaningful \( n_{\text{corr}} \), one has to account for all effects that could change the number density, either related to the cluster or otherwise. First, masks around bright stars reduce the number of observable galaxies. At large distances, their impact is averaged out and only affects \( n_b \). At smaller distance, we excised the radial range with prominent stars from the fit. This was necessary in the Bullet cluster field between 10 and 15 arcmin and in the RXJ field between 4 and 7 arcmin.

Second, the lensing-induced magnification could alter the observable number of galaxies, depending on the faint-end slope of the luminosity function. Even for clusters as massive as this, the magnification effect on the number counts is prominent only at small cluster-centric distances, which we will exclude from our lensing mass estimates in Section 5.1, and is thus left uncorrected.

Third, the high density of large galaxies in the core region of clusters prevents us from detecting background galaxies or measuring their shapes accurately. In other words, the success fraction of shape measurements declines towards the center, which could hide a substantial cluster-member contamination for the sample of galaxies we can measure shapes of. We assess the success probability \( p_{\text{suc}}(r) \) with the newly developed code Balrog\(^{11}\) that allows us to insert artificial galaxies into our coadd images and compare the resulting catalogs with the input catalogs (Huff et al., in prep). In particular, we perform object detection and shape measurement, including any additional cuts, identically to the actual data analysis and then infer the rate of galaxies with acceptable shapes as a function of cluster-centric distance. Since we can only count galaxies after their numbers \( n_{\text{gal}} \) have been reduced due to blending with the cluster galaxies, we need to correct for the effect according to

\[
n_{\text{corr}}(r) = \frac{n_{\text{gal}}(r)}{p_{\text{suc}}(r)},
\]

which brings these numbers, and hence the parameters of the fit in Equation 4, back to values they would have without the presence of cluster-member galaxies. The dimensionless term \( 1/p_{\text{suc}} \) is shown for each clusters as black line in the bottom panels of Figure 2, where we contrast it with the number density of redMaPer-detected galaxies (blue lines). We take the steeper profile of the \( p_{\text{suc}} \) boost factor as an indication that the main difficulty for measuring shapes in the central cluster regions stems from the existence of very large cluster galaxies, foremost the BCG, not just their increased number density.

We remark that the approach outlined here is very similar to the treatment in Applegate et al. (2014), in that the measured number densities are used to estimate the cluster-member contamination. But where they had to resort to proxies to estimate the success rate of their shape measurements, we actually measure \( p_{\text{suc}} \) directly from our images.

3.4.2 Photo-z inaccuracies

The redshift estimate \( z_{\text{phot}} \) still enters directly into \( \Sigma_{\text{crit}} \), effectively treating \( z_{\text{phot}} \) as the true redshift of the source \( z_s \). This is wrong in three ways. First, \( \Sigma_{\text{crit}} \) is a non-linear function of \( z_s \), therefore even symmetric uncertainties \( \Delta z_{\text{phot}} \) as estimated in Section 3.3 lead to biased results for \( \Sigma_{\text{crit}} \) and thus for \( \Delta \Sigma \), the net effect of which is an underestimate of \( \Sigma_{\text{crit}} \) that strongly rises with \( z_{\text{phot}} \to z_s \). Second, one can furthermore imagine that occasionally \( \Delta z_{\text{phot}} > 0.2 \), so that galaxies that are actually in front of the cluster make it into our background sample defined by Equation 3. And third, the estimated photo-zs (or their errors) could be catastrophically wrong, so that we may misestimate \( \Sigma_{\text{crit}} \) with consequences yet to be determined.

We make use of the spectroscopic reference sample again and compute the true redshift distribution \( p(Z_s | z_{\text{phot}} \in Z) \) of sources in photo-z slices \( Z \) and spectroscopic slices \( Z_s \) of width 0.1. Adopting a strategy closely related to Blazek et al. (2012), we determine the correction factor

\[
\zeta^{-1}_{Z} = \frac{\sum_{Z_s} p(Z_s | z_{\text{phot}} \in Z) \Sigma_{\text{crit}}^{-1}(Z_s)}{\Sigma_{\text{crit}}^{-1}(Z)},
\]

\(^{11}\) https://github.com/emhuff/Balrog
whereby we mean \( \Sigma_{\text{crit}}(Z) = \Sigma_{\text{crit}}(z_{\text{phot}} \in Z) \), and likewise for the spectroscopic slice \( Z_s \). Applying this correction,

\[
\Sigma_{\text{crit},sz} = cz \Sigma_{\text{crit},sz}.
\]

we control for the three photo-\( z \) errors on \( \Delta \Sigma \) mentioned above at the level of \( \Delta z_s = 0.1 \), which is more fine-grained than our cluster-member contamination correction from Section 3.4.1. For the remainder of this work, we will only work with corrected \( \Sigma_{\text{crit}} \) values according to Equation 8 without specifying it explicitly. A quantitative assessment of the amplitude of all corrections introduced in Section 3.4 is given at the end of Section 5.1.

4 WEAK-LENSING ANALYSIS

For this paper, we adopt a shape-measurement strategy, in which we perform the analysis on single-filter coadds and combine the results from the \( r, i, z \) filters at the ellipticity level. While neither statistically nor systematically optimal,\(^\text{12}\) working with coadded images, commonly done in cluster lensing studies, allows us to perform the shape measurements – of both stars and galaxies – at relatively high significance, the importance of which will become evident in the next section.

4.1 PSF modeling

Ordinarily, one models the PSF and its spatial variations simply by building a model from all available stars in the field. Unfortunately, PSF modeling for DECam is somewhat more complicated because its thick deep-depleted CCDs exhibit a mild flux dependence in the registration of charges. This is believed to be due to the accumulation of charges in the pixels altering the local electric field, effectively creating a repulsive force that scales linearly with the amount of charge already present (Antilogus et al. 2014).\(^\text{13}\) The most apparent consequence is a flux dependence of the PSF width, hence the effect being dubbed the “brighter-fatter relation”. The effect is not quite isotropic, having a preferred alignment towards the readout direction.

A proper correction of this effect would involve modeling the redistribution of charges and locally re-assigning image counts between neighboring pixels to recreate the theoretical “zero-flux” shape of stars and galaxies. Such an approach is currently under development, but goes beyond the scope of this paper. In the following sections, we will adopt a simpler approach, in which we eliminate the brightest stars when building the PSF model (see Appendix A for details). As they carry most of the photons, we need to compensate by pushing the star selection for the PSF model to fainter levels, where identification and shape measurement of stars can be performed much more reliably on coadded images.

\(^{12}\) The potential errors of the image coaddition could be avoided if the shape measurements are done on single-epoch images (cf. Miller et al. 2013), provided that the PSF can be modeled well with stars of lower significance. One can also reduce the noise-induced shape measurement biases by performing simultaneous shape fitting of all available exposures, even across filters. Both of these improvements are pursued for further lensing analyses in DES but go beyond the scope of this paper.

\(^{13}\) We note that, in principle, the cosmic-ray rejection in our image coaddition procedure (cf. Section 2.2) can introduce a similar effect (Heymans et al. 2012, their section 2.2). However, the change of the stellar width as a function of stellar flux is consistent with the one observed by Antilogus et al. (2014) on single-epoch images. We therefore conclude that our clipping procedure does not significantly affect the observed stellar widths.

4.1.1 Star selection and PSFEx models

The first step of building a PSF model is to select a sample of stars, from which the shape of the PSF can be reliably inferred. Due to the large size of DECam, we need to be able to tolerate considerable variations of size and ellipticity of actual stars in this initial selection to avoid forming an incomplete model of the PSF.

We work with the coadd catalogs from SExtractor and perform a first-pass selection of stars in the size-magnitude plane (to be precise, in the plane of MAG_{\text{AUTO}} and both FHWM_{\text{IMAGE}} and FLUX_RADIUS), which yields mostly isolated stars, well suited for PSF measurements. To avoid saturated or noise-dominated stars, we could restrict the selection to objects with MAG_{\text{AUTO}} \in [15, 21.5], but the flux-dependence of the PSF forces us to introduce a much more restrictive selection MAG_{\text{AUTO}} \in [18, 21.5] to prevent the brightest stars from rendering the PSF model inappropriate for the bulk of fainter stars and galaxies (cf. Figure A1 for an example with the full range of stellar magnitudes).

We improve upon this first pass by requiring that stars be on the stellar branch in each of the filters \( r, i, z \), which makes for a cleaner selection at faint levels and avoids the inclusion of blended stars whose faint companion is a drop-out galaxy for bluer filters. As a last step, we build a locally smoothed map of the FLUX_RADIUS measurements of the stars selected so far and reject 3\( \sigma \) outliers. This localized selection is necessary for the wide-field imager DECam since stellar sizes increase considerably towards the edges of the field (cf. bottom-left panel of Figure 3) so that mildly blended objects in the inner region could have passed the first selection with global size-magnitude cuts.

The procedure yields a very clean sample of objects, whose sizes are characteristic of relatively bright stars in the entire field with no noticeable contamination of neighboring objects. This selection is then passed on as input catalog to PSFEx (Bertin 2011), run with BASIS\_TYPE=PIXEL\_AUTO, BASIS\_NUMBER=20 and varying polynomial degree PSFVAR\_DEGREES \in \{4, 8, 12, 16\}. The pixel-based model is therefore formed by polynomial interpolation of 20 \( \times \) 20 super-resolution cells, taken from 48 \( \times \) 48 pixel cutouts.

4.1.2 PSF modeling tests

Figure 3 shows one example of our PSF modeling approach, displaying stellar and model ellipticities in the top row and corresponding sizes in the bottom row. We can see that both sizes and ellipticities tend to increase towards the field edges and that there are structures present at various scales in both measurements. We therefore assess the validity of the PSFEx models by the distribution of residuals and their cross-correlation functions, shown in the third and fourth column of Figure 3, respectively.

Following Rowe (2010) (although using slightly different notation), we define the residual autocorrelation and the signal residual cross-correlation functions of the (complex) ellipticity measurements,

\[
\rho_1(r) \equiv (\Delta \epsilon_i^* \Delta \epsilon_j)_{ij},
\]

\[
\rho_2(r) \equiv (\epsilon_i^* \Delta \epsilon_j + \Delta \epsilon_i^* \epsilon_j)_{ij},
\]

where the average comprises pairs of stars \( i, j \) with separations \( r \), and the residuals are defined as \( \Delta \epsilon = \epsilon - \epsilon_{\text{mod}} \), the difference of stellar and model ellipticities. Conjugation of the complex ellipticity is notated as \( \epsilon^* \).
For the size measurements $s$, we introduce a third diagnostic function similar to the above,

$$\rho_3(r) = \left(\frac{\Delta(s)}{s^*}\right) \left(\frac{\Delta(s)}{s^*}\right)_{\epsilon_1}$$

(10)
based upon the fractional error in $s^2$. These two sets of diagnostic functions check for the anisotropic and the isotropic validity of the PSF model and hence for the amount of systematic shear misestimation introduced by insufficient PSF correction.

After defining the diagnostic functions, we need to answer the question: how small do they need to be? In Appendix B, we work out the details, but the guiding principle is as follows. The error on the measured (deconvolved) shapes will be related to errors in the PSF model via a factor $T$ that compares the PSF size to the galaxy size. If we limit this PSF-induced shape measurement error by the intrinsic shape scatter of the background sample $\sigma_\epsilon$, which provides the fundamental limit to the statistical power of the lensing data, we can solve for the maximum tolerances of these diagnostics

$$\rho_1(r) + \left[\sigma^2_\epsilon + \langle\epsilon_\star\epsilon_\star\rangle(r)\right] \rho_0(r) < \frac{T^2 \sigma^2_{\epsilon}}{n_{gal} \pi (R_{max}^2 - R_{min}^2)},$$

(11)

where $T = P_y (\frac{s_{gal}}{s_\star})^2$, with $P_y$ denoting the shear responsivity and $s_{gal}$ the size of the galaxy prior to convolution with the PSF, $n_{gal}$ is the number density of galaxies with shape measurements, for which we adopt $n_{gal} = 10$ arcmin$^{-2}$ per filter as typical value (cf. Section 4.3). The limits of the radial bin centered at $r$ are given by $R_{max}$ and $R_{min}$. As we point out in Appendix B, we drop the requirement on $\rho_2$ as it does not exhibit substantial diagnostic power.

Measuring these diagnostics and comparing them to the maximum tolerance then allows us to determine how large a typical galaxy has to be so that the PSF-induced errors do not dominate over the shape scatter. In units of m\textasciicircum{circ}h\textasciicircum{circ}\textasciicircum{circ}n's FHWM\_RATIO (cf. Section 4.2 for the definition and Equation B8 for the relation to $T$), our best models can use galaxies with FHWM\_RATIO $> 1$. At our typical seeing of $\lesssim 1$ arcsec, this limit corresponds to $s_{gal} \approx 0.4$ arcsec, in line with measurements for the typical sizes of galaxies at our depth based on deep HST imaging in Miller et al. (2013, cf. their Fig. 1). We do not consider PSF models, where that requirement would go beyond FHWM\_RATIO $= 1.2$ ($s_{gal} > 0.65$ arcsec), the size cut, for which the shape measurement code is well tested (see next section). All fields and filters that qualify under this requirement are listed with a $\checkmark$ in Table 2.

---

14 by which we mean the sum of the flux-normalized second-order moments $\sigma^2 = \frac{1}{T} (Q_{11} + Q_{22})$, or equivalently the intensity-weighted second moment of the radius $\langle r^2 \rangle_\rho$ averaged over image $I$.

15 In Section 4.3 we will introduce additional lensing weights that effectively reduce $s_{gal}$ by 10-15%, which means that our PSF diagnostics limits are slightly over-conservative.
In terms of complexity, the best-performing PSFEx models have polynomial degree between 8 and 16, with a majority at 16. In addition and as replacement of the proposed role of $p_2$ in Rowe (2010), we performed a cross-validation study, in which we build a model using only a subset of the stars and then compute the diagnostically significant properties of the remaining stars. Even with the highest polynomial degrees, the models showed no indication of overfitting the data and, with the numbers of stars we provided, produced stable results in the analyzed areas of each field.

To our knowledge, this is the first time that tolerances for PSF model diagnostics have been utilized to predict what size galaxies need exceed so that their shapes can be sensibly determined. The approach we have adopted here is conservative in three distinct ways. First, because we require the PSF models to stay within their tolerances at all scales, the actual PSF errors are smaller than our limits at most scales. Second, by calculating the tolerance at the limit of the smallest galaxies, the majority of the source sample will be less affected by PSF errors than predicted. And third, as we show in Section 4.3, the final shape catalogs are combined from different filters, so that the variation of PSF properties between filters enables a partial cancellation of the PSF-induced errors. We therefore consider the resulting shapes not to be dominated by PSF systematics, a claim we are going to review in Section 4.4.

### 4.2 im3shape measurements

For the weak-lensing shear analysis presented in this paper, we use the publicly available galaxy shape measurement code im3shape (Zuntz et al. 2013). By maximizing the likelihood, it fits a PSF-convolved two-component bulge-plus-disc galaxy model to measure the ellipticity of each galaxy. In particular, we model galaxies as a sum of co-elliptical Sérsic (1963) profiles described by seven free parameters: ellipticity ($\epsilon_1$, $\epsilon_2$), position ($x_0$, $y_0$), disc half-light radius ($r_d$), bulge and disc peak flux ($A_b$, $A_d$). We set the indices of the Sérsic profiles to 1 for the disc component and 4 for the bulge component. The bulge-disc size ratio is also kept fixed at 1.0.

To counter the adverse effects of aliasing and avoid up sampling biases we render intermediate model images at higher resolution as described in detail in 4.1 of Zuntz et al. (2013), choosing im3shape’s up sampling conservatively as up sampling = 5, n_pixels_to_upsample = 8, and n_central_pixel_upsampling = 7 with a postage stamp of size stamp size=37 pixels. This is done for both the galaxy model image and the PSF image sampled from the PSFEx model at the galaxy position estimated with SExtractor. The convolution of the two is then performed in Fourier space.

There are notable complications in our use of im3shape here compared to the simulation study presented by Zuntz et al. (2013):

- **Neighboring objects.** The flux of nearby objects affects shape measurement and leads to biases if not treated carefully. To this end, we make use of the segmentation map provided by SExtractor: we give zero weight to all pixels that are assigned to another identified object within the processed image stamp.

- **Background treatment.** Although the single-filter coadd images are globally background-subtracted by SWarp, we find a non-zero local background for a few postage stamps where the global background subtraction remained insufficient. Therefore, we perform a local background estimation by averaging those pixels within the postage stamp that have not been assigned to any detection. The resulting value is then subtracted as a constant from all pixels within the analyzed image.

We process each single-filter coadd image independently. For each image we run on all detected objects (with the exception of very bright and very faint objects). To clean the final shear catalogs, we first perform a star-galaxy separation based on the im3shape-estimated FWHM_RATIO between the pixel-PSF-convolved model image and the PSF image. The FWHM of a pixel-PSF-convolved galaxy model is estimated from its centered, noise-free model image with its ellipticity set to zero. The FWHM_RATIO is in effect a measure of the pre-seeing mean radius of the source, and hence we expect cuts based on this quantity to be free of first-order biases toward alignment with the PSF. All objects with FWHM_RATIO < 1.1 are considered unreliable for shape measurement, often stars, and are excluded from further processing. We also remove shape measurement outliers by applying additional cuts based on im3shape fit results. In particular, we apply cuts for the following parameters: the best-fit likelihood value, the minimum and maximum model value (per pixel), the minimum and maximum residual value (per pixel), the change in the estimated centroid position, and the disc half-light radius. The cuts are adjusted for each coadd image and are only meant to reject obvious failures of the shape measurement process.

#### 4.2.1 Noise-bias calibration

Shape measurements are affected by a prominent bias when the galaxy images become noisy (e.g. Massey et al. 2007). This is a consequence of the observable, the galaxy ellipticity, being non-linearly related to the flux in each pixel and applies to model-fitting methods and moment-based measures of the ellipticity alike (Melchior & Viola 2012; Refregier et al. 2012; Kacprzak et al. 2012).

To calibrate im3shape’s response to noise bias we simulate mock galaxies, using the GalSim framework. In particular, we adopt the methodology of Mandelbaum et al. (2012) and degrade high-resolution and high-significance images from COSMOS to the DECam resolution and magnitude limit (cf. Figure 1). We approximate the coadd PSF by a circular Moffat (1969) profile with seeing values $[0.7, 0.8, 0.9]$ arcsec, spanning the expected range of our observing conditions. Applying exactly the same cuts as for shape catalogs from the coadd images, we have verified that both magnitude and size distributions of the simulated galaxies closely match the observed ones. Adding an artificial shear $\gamma$ of order 5%, we can infer the shear response

$$m_n = \frac{\partial \epsilon}{\partial \gamma} \quad (12)$$

as a function of the signal-to-noise ratio SNR and FWHM_RATIO. We believe these two parameters to largely determine the shear response, and by working with size ratios we render this calibration mostly insensitive to the observed PSF widths that occasionally exceeded the simulated range. The result is shown in Figure 4. At high SNR, the shear can be measured in an unbiased fashion for all galaxy sizes, whereas the noise bias gets progressively worse for lower SNR, scaling roughly as $\text{SNR}^{-2}$, consistent with findings of Bernstein & Jarvis (2002). It is counter-intuitive that the smallest galaxies show the least amount of bias. Also, at very low SNR the larger galaxies show an intriguing upturn. We interpret both as

© 2015 RAS, MNRAS 000, 1–20
Figure 4. Noise bias on the multiplicative term \( m_n \) of the shear response as a function of \texttt{im3shape}'s SNR for different values of the galaxy FWHM\_RATIO. The solid lines are even-order polynomial fits to the data (cf. Equation 13). The bottom panel shows the SNR distribution of galaxies with shape measurement from any single-filter coadd image, averaged over all fields and \( riz \) filters.

higher order effects of the noise bias. A decrease in noise bias for smaller galaxies is plausible, particularly for a mixture of biases with different signs at different orders in SNR and FWHM\_RATIO, with perhaps some fortuitous cancellation for the smallest galaxies we plot. According to Kacprzak et al. (2012), even only orders of SNR can appear in the noise-bias relation, therefore we attempt to parameterize the dependence with the following polynomial model,

\[
m_n = c_0 + c_2 \text{SNR}^{-2} + c_4 \text{SNR}^{-4},
\]

whose best-fit parameters are listed in Table 3. The applied noise-bias corrections are taken from these fits in each of the size bins.

We also note that the shear response of Equation 12 is assumed to be linear in the shear. Large shears, as encountered close to the centers of clusters, may introduce a non-linear response, which would be overseen by our calibration approach. However, for the analysis in Section 5 we will exclude these inner regions and restrict ourselves to shear values, for which \texttt{im3shape}'s performance was tested by our simulations and others (e.g. Kitching et al. 2012).

4.3 Final catalog creation

For each cluster field we include the shape catalogs for all filters \( f \) that passed the PSF modeling requirements from Section 4.1.2 (cf. Table 2 for the list). Based on SExtractor measurements, we enforce additional cuts to clean the catalogs from potentially problematic measurements: \texttt{FLAGS} = 0 and \texttt{CLASS\_STAR} < 0.8. We furthermore exclude areas at the edges of the fields, where the coverage is not homogeneous across filters, giving rise to the “picture frame” geometry shown in the left panels of Figure 3. We also mask out stars detected in the Tycho-2 catalog (Hog et al. 2000) with magnitude-dependent circular and hand-crafted bleed trail masks to avoid saturation features and local sky-background variations that could affect the photometry or the shape measurements. The remaining sample is shown as “Clean” in Figure 1.

On top of the selection inherent to \texttt{im3shape} success, we restrict the shape measurements to \( \text{SNR} > 5 \) and \( \text{FWHM}\_\text{RATIO} > 1.2 \) in concordance with limits on both the PSFEx-model quality and the shape calibrations in Section 4.2.1. For each remaining galaxy \( j \), the shapes are combined from all available filters \( f(j) \) according to their \texttt{im3shape} weight \( w_3(j,f) \),

\[
\epsilon(j) = \frac{\sum_{f(j)} m_n(j,f)^{-1} \epsilon(j,f) w_3(j,f)}{\sum_{f(j)} w_3(j,f)}.
\]

This filter-combined ellipticity maximizes the number of galaxies with shape measurements and reduces the variance due to pixel noise in each ellipticity estimate derived from more than a single filter. The resulting catalog forms the basis for all subsequent analysis and is denoted as the “Shapes” sample in Figure 1. The number density \( n_{gal} \) of this catalog ranges from 9 to 12 arcmin\(^{-2}\), with the best available seeing in each field being the dominant factor of that variation. This is consistent with the expectations for the full-depth DES imaging data (The Dark Energy Survey Collaboration 2005). Only the coadd images of the additional cluster Abell 3261 do not reach the nominal full depth of 10 exposures, resulting in a reduced \( n_{gal} = 8 \) arcmin\(^{-2}\).

Note that the noise-bias correction \( m_n(j,f)^{-1} \) in Equation 14 depends on SNR\((j,f)\) and FWHM\_RATIO\((j,f)\) as described in Section 4.2.1. The weight takes both statistical and measurement variances into account (e.g. Hoekstra et al. 2000, their Eq. A2),

\[
w_3(j,f) = \frac{\sigma^2}{\sigma^2 + \left[ 0.1 \times \frac{1}{m_n(j,f)} \text{SNR}(j,f)^{-1} \right]^2},
\]

where we have adopted an estimator for the measurement error \( \sigma \), that scales inversely with SNR and accounts for variable amounts of noise-bias correction. This estimate may be on the conservative side, but has performed well in simulations, where a full likelihood exploration for the parameters was available. For the weight \( w_3(j) \) of the combined shapes, we stick to the formula above, but replace \( \text{SNR}(j,f) \) with \( \sum_{f(j)} \text{SNR}(j,f) \).

When we apply the weights to the shape catalog, the effective number density \( n_{eff} \approx 0.87 \times n_{gal} \), while both shape scatter and mean redshift of all galaxies with shape measurements are only mildly (i.e. of order 5\%) reduced by the weighting, \( \langle \epsilon_{\text{shape}} \rangle = 0.7 \) and \( \sigma \epsilon = 0.3 \). We emphasize that because of anticipated changes in the shear-measurement pipeline for future studies, these numbers are only roughly indicative of the DES performance and should therefore be treated with due caution.

Applying the photo-z cut of Equation 3 finally yields the shape catalog for the background sample, labelled as “BG” in Figure 1.

4.4 Consistency tests

While not strictly necessary for the lensing analysis in Section 5, we choose to express the measurements in \( \Delta \Sigma(r) \) rather than in the actual observable, the shear \( g = \langle \epsilon \rangle \). This physical quantity should be invariant under choice of source populations, at least ideally.

| FWHM\_RATIO | \( c_0 \) | \( c_2 \) | \( c_4 \) | \( N_{gal} \) [\%] |
|-------------|-------|-------|-------|----------|
| \([1.20,1.30]\) | \( 1.010 \pm 0.012 \) | \( -3.9 \pm 3.6 \) | \( -64 \pm 129 \) | 24.2 |
| \([1.30,1.40]\) | \( 1.001 \pm 0.012 \) | \( -17.2 \pm 3.4 \) | \( 229 \pm 127 \) | 19.0 |
| \([1.40,1.50]\) | \( 1.019 \pm 0.013 \) | \( 30.2 \pm 3.5 \) | \( 587 \pm 130 \) | 15.3 |
| \([1.50,1.60]\) | \( 1.028 \pm 0.016 \) | \( -30.5 \pm 4.1 \) | \( 498 \pm 150 \) | 12.0 |

It allows us to slice the background sample in various ways and thereby to test whether the shear measurements and the various calibrations are accurate. To work with a sufficient number of galaxies, we combine the four clusters by stacking them at their respective (BCG) centers. The test results are shown in Figure 5.

First, we check whether the typical SNR-dependence of weak-lensing measurements is corrected by our calibrations from Section 4.2.1. The left panel of Figure 5 shows that there is no strong trend visible when varying m3shape’s S/N parameter, implying that our calibration was indeed successful. In terms of weak-lensing mass (see methodology in Section 5.1), we have less than 10% variations between each subset and the entire stack. Note that we slice the final catalog, where ellipticity measurements have been combined according to Equation 14, therefore the SNR is given as the sum over the measurements in each filter. The pivotal value $\sum_{i} S/N = 30$ is chosen here because it yields $\text{SNR}(f) \approx 10$, which, according to Figure 4, separates galaxies with substantial levels of noise-bias corrections from those with a much milder correction.

Second, we split the sample according to the reported photo-z of each source. As we have corrected for the redshift dependence of the measured shear by converting to $\Delta \Sigma$ (see Section 3.4 for the details and calibrations we applied to the raw photo-z values), we should not see any variation induced by the change in distances in Equation 1, and indeed there is no recognizable in the second panel of Figure 5. Quantitatively, we find the upper redshift slice to have a higher mass estimate of about 15%, whereas the lower panel of Figure 5. Quantitatively, we find the upper redshift slice to have a higher mass estimate of about 15%, whereas the lower redshift and the mass estimate seems to be well characterized. The upper redshift slice has a mild size dependence of the signal seems to be well characterized. The upper redshift slice has a mild size dependence of the signal seems to be well characterized.

Finally, the last panel of Figure 5 shows the lensing signal if we only use the shape measurements from single filters instead of combining them according to Equation 14. Using single filters constitutes a drop-out technique, where galaxies are more likely measurable in redder filters if they are at higher redshifts. Since the redshift dependence of the signal seems to be well characterized (second panel), we expect consistent measurements here, too. However, uncorrected effects related to the CCD (e.g. prominent fringing in the $z$-band) or the instrument in general could interfere, but to the limit of this test we can rule this out: the mass estimates agree to better than 10% across filters. This leads us to the non-trivial conclusion that DECam images taken in each of the $riz$ filters seem equally suitable for shape measurements.

Note that this methodology effectively constitutes a sequence of null tests, even though we inspect the actual signal. We could have subtracted the mean signal to render it a proper null test, but we choose to leave it in since some of the systematics could scale with, for example, the lensing strength or the source density, so it may help to actually see the mean cluster signal to gauge the dependency on cluster-centric distance $r$. Larger cluster samples investigated in forthcoming DES analyses will substantially sharpen these consistency tests and allow us to detect potential shape measurement problems with much higher precision.

5 SHEAR PROFILES AND LENSING MASSES

We now measure the lensing masses by fitting a radial profile to the tangential shear signal, centered on the BCG coordinates as listed in Table 1.

5.1 NFW profile fits and lensing masses

To obtain estimates of cluster masses, we assume the density profile described first by Navarro et al. (1996, NFW). The three-dimensional density $\rho(r)$ of the NFW profile at radius $r$ is given
We evaluate the posterior distribution of the likelihood of any model can be calculated from the shear catalogue by comparing our data to the observed (as opposed to an unlensed) distribution of shapes. The profile can alternatively be expressed in terms of the mass $M_{200c}$ and concentration $c_{200c}$, instead of the central density $\rho_0$ and scale radius $r_s$. Here $r_{200c}$ denotes the radius of a sphere that comprises an overdensity of 200 times the critical density at the redshift of the cluster. The projected density and gravitational shear of the NFW profile are given in Bartelmann (1996) and Wright & Brainerd (2000).

Assuming Gaussian errors on the shape estimates, the likelihood of any model can be calculated from the shear catalogue by means of the $\chi^2$ statistic. Given model predictions $\Delta \Sigma(r)$ for the lens and the measurements of component $\epsilon_j(r)$ of the ellipticity of galaxy $j$ tangential to the cluster center, the likelihood $L$ can be written as

$$L = \frac{\rho(r)}{\langle \rho \rangle} \left( 1 + \frac{r}{r_s} \right)^2$$

where $\langle \rho \rangle$ is the average density of the galaxy cluster.

In Figure 6 we show the individual shear profiles and 100 randomly chosen sample projections onto the data to demonstrate the range of viable models after an initial burn-in phase. Parameter uncertainties, the NFW profile constitutes an acceptable model for all clusters. We also want to point out that the B-mode, denoted as $\gamma_s$, in Figure 6, is statistically consistent with zero for all clusters, although some moderately large fluctuations occur.

It is typical for pure weak-lensing measurements that the concentration is only poorly constrained (e.g. Postman et al. 2012), a tendency that we have even exacerbated by excluding the inner 3 arcmin. This highlights the potential importance of a concentration prior, a situation in which the significant differences in the literature between concentration-mass relations derived from different simulations or observational studies may appear worrisome. However, deviations of the assumed relation from the truth only mildly impact the weak-lensing mass measurement (e.g. Hoekstra et al. 2012, their section 4.3). Indeed, we find no significant differences of the marginalized results using the Duffy prior or an entirely flat prior within $0 < c_{200c} < 8$.

Comparing our $M_{200c}$ estimates with previous results listed in Table 4, often based on substantially deeper data, we find good agreement for RXC J2248.7-4431, where the mass estimate in Gruen et al. (2013) is within our 68% confidence region. Two recent analyses of the same data – together with magnification (Umetsu et al. 2014) or HST strong- and weak-lensing constraints (Merten et al. 2014) – yield reduced estimates of $M_{200c}$, which are fully consistent with our result.

For the Bullet cluster, our mass estimate is rather poor due to a fairly low $n_{gal}$, but we can recover the result of Clowe et al. (2004) within errors. This comparison is, however, not as straightforward as it seems. The original ground-based VLT data in Clowe et al. (2004) had a field of view of only 7 arcmin, hence the radial range employed by Applegate et al. (2014) but extends somewhat farther out to reduce the shot noise from the rather low $n_{gal}$ of our data. The NFW profile is not a good fit to lensing measurements at such large distances because it lacks the two-halo contribution from structures associated with the clusters. However, the resulting bias is only of order 10% (Oguri & Hamana 2011, their Fig. 4), which will certainly be below our measurement accuracy.

Figure 6. Surface density contrast $\Delta \Sigma = \Sigma_{gal} \gamma_s$ profiles (black) for each of the four cluster fields and 100 random MCMC sample projections onto the data (light gray) after an initial burn-in phase. The fit range was restricted to $3 < r < 15$ arcmin. The B-mode $\Sigma_{gal} \gamma_s$ is shown in red.
probed there is almost entirely excluded in our fit that starts at 3 arcmin. We therefore acknowledge the similarity of our mass estimates with the literature value, but do not consider this a powerful result.

The situation is different for SCSO J233227-535827, where the shear profile is more regular and our mass estimate is better constrained. Our estimate is in excellent agreement with the weak-lensing analysis from Gruen et al. (2013). Our central value is about twice as high as the estimate from High et al. (2010), which lacks a confidence estimate, to $M_{200c} = 4.9 \pm 3.3 \pm 1.4$ (High et al. 2010, R).

We conclude this section with a test on the robustness of the mass estimate against uncertainties in the numerous calibrations we have employed. To assess the impact of the calibrations, we repeated the NFW-profile fitting without the calibrations. The cluster-member contamination correction from Section 3.4.1 alone increases the mass estimates by less than 5% as it only affects the galaxies within 5 arcmin, and our fits start at 3 arcmin. The photometric redshift recalibration from Section 3.4.2 yields a global boost of the lensing signal by 5-10%. The largest impact stems from the noise-bias correction (Section 4.2.1), which globally increases the inferred shear by $\sim$20%. The sum of all these calibrations amounts to a factor $\sim 2/3$.

### 5.2 Richness-mass relation

An obvious additional cross-check for the data in this work is to compare it with the mass-richness relation for low-redshift clusters. Rykoff et al. (2012) constrained it with maxBCG (Koester et al. 2007) clusters in the range $0.1 \leq z < 0.3$ with a very similar richness estimator $f$ to the one we employ here. Although their redshift range only covers two of our clusters (the other two are at slightly higher redshift), we expect that deviations would more likely stem from our large measurement errors on the weak-lensing mass than from any possible redshift evolution of that relation.

We list the redMaPPer-estimated richness and redshift estimates in Table 4 and note that for the three clusters, for which we have spectroscopic redshifts, redMaPPer provides excellent redshift estimates, with deviations within $\pm 2\sigma$ in all cases. We take this as an indication that our overall photometric calibration (Section 3.1) and the red-sequence (Section 3.2) calibration were successful. In Figure 7 we compare the richnesses with the weak-lensing masses from Figure 6 and the best-fit solution from Rykoff et al. (2012, their Eq. B5)

$$\ln \left( \frac{M_{200c}}{10^{14} h^{-1} M_\odot} \right) = 1.48 (1 \pm 0.33) + 1.06 \ln \left( \frac{f}{0.6} \right)$$

and find that our measurements indeed agree with the expectations, within the considerable scatter both measurements exhibit.

### 6 MASS AND CLUSTER GALAXY DISTRIBUTIONS

We now move from spherically averaged masses to two-dimensional maps of the weak-lensing mass and the cluster galaxies. We have seen in Section 5.1 that the NFW profile is an acceptable fit to the measurements. In detail, that is not even expected as

---

21 We note that Rykoff et al. (2012) made simplifying assumptions about the absence of an error on the slope in Equation 18. We therefore refer to their Appendix B for a discussion of the limitation of the inferred mass-richness relation.
the NFW profile only describes the average radial profile of dark matter halos in simulations, incapable of reproducing the complex structures massive clusters often exhibit (e.g. Merten et al. 2011; Medezinski et al. 2013). We are particularly interested in the environment of these clusters, using DECam to follow the filamentary structures from which the clusters accrete out to distances normally not accessible to dedicated cluster-lensing studies on imagers with smaller fields of view.

We start the inspection of the cluster fields visually at the central 5 × 5 arcmin² of each cluster in the left column of Figure 8, where we can see the BCG and other bright cluster members. In all four clusters, we can see that several of the obvious cluster member galaxies tend to line up along one axis that coincides with the orientation of the BCG. This long-known tendency (Sastry 1968; Carter & Metcalfe 1980) is still not entirely understood, but a plausible scenario entails that accretion of satellite halos along filaments determines the cluster major axis, and the BCG orients itself accordingly (e.g. Hao et al. 2011, and references therein).

### 6.1 Mass maps

To perform the mass reconstruction of the galaxy clusters, we move further out to cover 30 arcmin, a scale typical of weak-lensing studies of individual galaxy clusters, and employ the aperture-mass technique from Schneider (1996). It exploits that a local estimate of the convergence $\kappa(\theta) = \Sigma(\theta)/\Sigma_{\text{crit}}$ can be obtained by summing up all ellipticity measurements $\epsilon(\theta_j)$ inside of a circular aperture,

$$M_M(\theta) = \sum_j Q(\theta - \theta_j) \epsilon(\theta_j).$$

(19)

Here the tangential component of the ellipticity $\epsilon_t$ is calculated with respect to the center $\theta$ of the aperture, not the center of the cluster as in Equation 17. Under the assumption of uncorrelated Gaussian noise in the ellipticities with variance $\sigma^2_{\epsilon_t}$, the variance of $M_M$ is given by

$$\sigma^2_{M_M} = \frac{1}{2} \sum_j Q^2(\theta - \theta_j) |\epsilon^t(\theta_j)|.$$  

(20)

So far we have not specified the weight function $Q$, and in fact we have considerable freedom in doing so, which allows us to demand additional desirable properties of the reconstructed mass maps. Since the noise contribution stemming from $\sigma^2_{\epsilon_t}$ is scale-free, the maximum $M_M/\sigma_{M_M}$ is achieved if $Q$ is identical to the signal we try to find, i.e. the tangential shear of the cluster (Schneider 1996; Bartelmann & Schneider 2001). Thus, we could turn the measured shear profiles from Figure 6 into templates for optimal individual shapes of $Q$, which would result in mass maps that are not easily comparable against each other. We therefore seek a common weight function $Q(r)$ with a single characteristic radius $R_{ap}$, knowing that we will sacrifice some statistical significance with this decision. We follow the design choices of Schneider (1996), which we find particularly suitable for this work for three reasons. First, he approximated the shear profile by an isothermal $\gamma \propto 1/r$ relation, which should allow us to capture the extended environment of these massive, and in parts even merging, clusters better than the steeper NFW profile. Second, the weight function excises an inner circle at $r < v_t R_{ap}$ to avoid regions where the relation between $\gamma$ and $k$ becomes nonlinear and shape measurements are rendered difficult due to bright cluster members. The same concern has led us to exclude the inner regions when fitting the NFW profile in Section 5.1. Third, Schneider (1996) also sets the outer edge of the weight function at $r > R_{ap}$ to allow the filter to operate on finite, and potentially masked, fields and to avoid the inclusion of truly uncorrelated structures, again corresponding to decisions we made earlier. To avoid a sharp cutoff at that outer edge, we let the filter roll off smoothly, starting at $v_t R_{ap}$, where $v_t < 1$. Considering the scale, over which we can find a noticeable shear signal in Figure 6, we choose $R_{ap} = 10$ arcmin, with an inner exclusion region of $v_t R_{ap} = 1$ arcmin and the onset of the roll-off at $v_t R_{ap} = 9$ arcmin. The exact form of the $Q(r)$ can be seen in Schneider (1996, eq. 34, Figs. 1 and 2). It is worth pointing out that in adopting these choices we employ a filter that is substantially different from those that attempt to maximize purity of blind detections from wide-field weak-lensing data (e.g. Maturi et al. 2005) by suppressing the influence of large-scale structure fluctuations: here we know where the clusters are and we want to probe the correlated material surrounding the clusters.

We present the resulting mass maps, i.e. maps of $M_M/\sigma_{M_M}$ centered on the location of the BCG, as contours in the middle panels of Figure 8. The mass maps of RXJ and SPTW1 show clearly significant peaks, exceeding 5.5 and 3.5$\sigma$ in their respective centers. For the Bullet cluster, the peak significance is not as prominent despite having an expected mass comparable to RXJ, but due to its highly non-spherical mass distribution, the spherical filter shape works against the signal, reducing its amplitude. Finally, even the least massive cluster, Abell 3261, shows up at the level of 3$\sigma$ in its mass map. The reduced significance of the latter two is caused also by a low $R_{ap} \approx 6$ arcmin² after background cuts.

We overlay the mass maps with redMaPPer-detected galaxies in groups with $\lambda > 5$, whose redshift estimates $z_g$ are consistent within $\pm 3\Delta z_g \lesssim 0.03$ with the main cluster redshift $z_{bcg}$ (see Section 3.2 for details). The distribution reveals the structure of the red-sequence galaxies within and around the main cluster halo.

Several aspects of the mass maps are remarkable. First, the mass maps clearly follow the red-sequence cluster-galaxy distributions. This is additional confirmation that the shape measurements indeed perform well since we expect mass to trace light. Second, the peaks in the mass maps do not always coincide with the cluster BCGs. For the Bullet cluster, the peak is placed roughly between the main cluster and the subcluster. Given our large smoothing scale, it is not surprising that the two peaks are effectively merged. Furthermore, even for single-peaked mass distributions, such shifts between the BCG and the most prominent mass peak are a consequence of sampling the shear field with a finite number of sources (e.g. Dietrich et al. 2012). Third, we note that additional peaks exist in the mass maps, occasionally reaching 2$\sigma$, that are not associated with the main cluster or other known clusters in the fields. To test the robustness of the mass maps we therefore run bootstrap resamplings of the lensed galaxies, which reveal that these peaks are largely spurious and depend on particular configurations of a small number of neighboring galaxies. In contrast, the peaks associated with the main clusters shift location by up to 2 arcmin but are otherwise robust under resampling.

### 6.2 Filamentary features

In the third column of Figure 8, we utilize the full DECam image and show the distribution of redMaPPer-detected groups for the entire usable area. We can see that the most massive clusters in the sample show a rich environment that seems connected to the central region and that reaches out to other clusters in the vicinity. From a hierarchical CDM structure-formation scenario, we expect such structures, called filaments, to be attached to and to act as bridges between clusters, especially the very massive ones (e.g. Bond et al. 2015).
Figure 8. 1st column: Multi-color image of the inner 5 arcmin. 2nd column: Weak-lensing aperture mass significance map of the inner 30 arcmin (contours, cf. Equation 19), overlaid with galaxies (black dots) in redMaPPer-detected groups with \( \lambda \geq 5 \) and redshifts of \( z_\lambda = z_\lambda^\prime \pm 3\Delta z_\lambda \). 3rd column: The same redMaPPer galaxies as in the 2nd column, but for the entire useable field of view of 90 arcmin. All panels are centered on the BCGs, the size of the previous (smaller) panel is indicated by black boxes in columns 2 and 3. From top to bottom: RXC J2248.7-4431, 1E 0657-56, SCSO J233227-535827, and Abell 3261.

© 2015 RAS, MNRAS 000, 1–20
Both cosmological simulations and spectroscopic surveys have revealed filaments with typical lengths of ten to dozens of Mpc (e.g. Alpaslan et al. 2014; Tempel et al. 2014). Of particular relevance to this study is that in simulations more than 80% of cluster pairs with distances of around 10 Mpc/h are connected by filaments (Colberg et al. 2005). In the RXJ field, there is another cluster in the same redshift slice, detected by redMaPPer with $\Delta = 41 \pm 2$ (red diamond in the top-right panel of Figure 8), at a distance of 40 arcmin to the south-west (12 Mpc in the plane of the sky), and a string of less massive groups that may constitute a mildly curved connecting filament. For the Bullet cluster, we can see another cluster at 28 arcmin to the north-west ($\Delta = 78 \pm 3$) and other correlated structure over 20 Mpc, assuming the entire galaxy distribution is aligned in the plane of the sky – a slight underestimation because it is known that at least the inner region is inclined by $10 - 15^\circ$ (Barrena et al. 2002; Markevitch et al. 2002). Structures that large have only been observed around a few other clusters, mostly at higher redshift than we probe here (e.g. Tanaka et al. 2009; Verdugo et al. 2012).

Without spectroscopic follow-up, we cannot prove that all shown redMaPPer-detected galaxies are indeed at the redshift of the main cluster or gravitationally interacting with the main halo. There are, however, additional aspects that support the notion that the shown structures are indeed real and associated with the clusters. redMaPPer determines the redshifts of the main cluster halos with high accuracy (compare Table 1 with Table 4), which implies that the overall photometric calibration performs well and that the red-sequence colors are properly calibrated for the DES photometry. This is consistent with the results from Rykoff et al. (in prep.) showing that groups with $\Delta \geq 5$ exhibit scatter of $\sigma_z \approx 0.015$ and negligible bias when compared to existing spectroscopic redshifts of clusters in the DES SV footprint. We can also split the light cone of the observed fields into thin redshift slices to test whether the structures are confined to the redshift of the main cluster halo.

The result for the RXJ cluster is shown in Figure 9. Note that this test is different from the right panels in Figure 8 in that we do not ask whether the redshift of the group is consistent with the main cluster’s at $3\Delta z$ (of each group), which potentially allows for an arbitrarily wide redshift range if $\Delta z \to \infty$. Instead, we only consider the central value $z_v$ of each group and fix the width of the slice at $\pm 0.03$, the typical value of $3\Delta z$ for groups with $\Delta \geq 5$. This way the influence of chance projections of groups with poorly determined redshifts can be suppressed. We can indeed see that the filamentary structure does not bleed into other slices. Also, apart from additional smaller clusters at different redshifts, the other slices are much less populated and do not show similarly prominent correlated structures. Tests of the other clusters yield similar results.

7 SUMMARY

In the study presented here we observed four galaxy cluster fields with the newly installed imager DECam and tested all data processing stages necessary for weak-lensing applications within the Dark Energy Survey. Even with early data observed during the Science Verification phase, we find the instrument and these pipelines to perform according to anticipated specifications and yield astrometry, photometry, and shape measurements adequate for the pathfinder analysis presented here, with no show-stoppers that preclude forthcoming science analyses. Most important in this work was to establish how to obtain reliable shape catalogs from DECam data, and we summarize our findings as follows:

- By jointly fitting for the astrometry of all exposures, we find 20 mas scatter in the astrometric solution of scamp across the entire focal plane.
- The PSF patterns are spatially fairly smooth across the focal plane and can be well modeled with PSFEx, provided that the brightest stars are discarded to limit the impact of the flux dependence of the PSF width. The majority of the coadd images have PSF model residuals in size and ellipticity that are subdominant compared to shape scatter up to separations of 1 degree.
- With suitably chosen cuts, mSHAPE yields shape measurements with a number density $n_{gal} \approx 10 \text{arcmin}^{-2}$ as expected for full-depth data at nominal seeing. The results are consistent when varying source flux, size, photo-z or the filter of observation.

These technical prerequisites enable us to utilize the large field of view of DECam to estimate weak-lensing masses and to map out the galaxy and mass distribution of the targeted galaxy clusters. Our scientific results are:

- We find weak-lensing masses for RXC J2248.7-4431, the Bullet cluster 1E 0657-56, and SCSO J233227-535827 that are in good agreement with previous studies. For clusters at higher redshift or dedicated high-precision lensing studies of individual systems, deeper imaging than the nominal DES depth of 10 $\times$ 90 seconds is advised.
- For the cluster Abell 3261, we provide the first redshift, richness, and weak-lensing mass estimates in the literature.
- The mass maps of all four clusters show their most significant peak at or close to the cluster BCG. Clusters with a visibly noticeable alignment of cluster member galaxies exhibit the same orientation also in the mass maps.
- Due to well-calibrated photometry, the red-sequence method redMaPPer detects these four clusters reliably. The redshift estimates of even much smaller clusters with $\lambda > 5$ are precise.
enough (Rykoff et al., in prep.) to form thin slices at the cluster redshift and to map out the distribution of red-sequence galaxies in the entire cluster environment. The most massive systems, 1E 0657-56 and RXC J2248.7-4431, show filamentary structures over about 1 degree, equivalent to about 20 Mpc at the cluster redshifts. If the presence of these structures can be confirmed, this technique can be employed in the DES main survey and enable efficient searches for large-scale filaments in the entire DES footprint without the need for full spectroscopic coverage.

The work presented here will form the basis of forthcoming analyses within DES, concerning e.g. the cluster-mass function, the calibration of mass-observable relations from optical richness, X-ray and SZE, and other more demanding lensing applications.

ACKNOWLEDGEMENTS

We are grateful for the extraordinary contributions of our CTIO colleagues and the DES Camera, Commissioning and Science Verification teams in achieving the excellent instrument and telescope conditions that have made this work possible. The success of this project also relies critically on the expertise and dedication of the DES Data Management organization.

Funding for the DES Projects has been provided by the U.S. Department of Energy, the U.S. National Science Foundation, the Ministry of Science and Education of Spain, the Science and Technology Facilities Council of the United Kingdom, the Higher Education Funding Council for England, the National Center for Supercomputing Applications at the University of Illinois at Urbana-Champaign, the Kavli Institute of Cosmological Physics at the University of Chicago, Financiadora de Estudos e Projetos, Fundação Carlos Chagas Filho de Amparo à Pesquisa do Estado do Rio de Janeiro, Conselho Nacional de Desenvolvimento Científico e Tecnológico and the Ministerio de Ciencia y Tecnologia, the Deutsche Forschungsgemeinschaft and the Collaborating Institutions in the Dark Energy Survey.

The Collaborating Institutions are Argonne National Laboratory, the University of Chicago, University College London, the DES-Brazil consortium, the Eidgenössische Technische Hochschule (ETH) Zürich, Fermi National Accelerator Laboratory, the University of Edinburgh, the University of Illinois at Urbana-Champaign, the Kavli Institute of Cosmological Physics at the University of Chicago, Financiadora de Estudos e Projetos, Fundação Carlos Chagas Filho de Amparo à Pesquisa do Estado do Rio de Janeiro, Conselho Nacional de Desenvolvimento Científico e Tecnológico and the Ministerio de Ciencia y Tecnología, the Deutsche Forschungsgemeinschaft and the Collaborating Institutions in the Dark Energy Survey.

APPENDIX A: PSF FLUX DEPENDENCE

The most important test for the PSF model is whether it can reproduce the sizes and ellipticities of observed stars in the field. When using the full range of stellar fluxes to inform the PSF model, we unfortunately register that the PSF width s is overestimated for the majority of all stars (see left panel of Figure A1). This is a direct consequence of the flux-dependent charge registration in the DECam CCDs, for which we currently do not yet have a chip-level correction. There is furthermore a broadening of the stellar ellipticity residuals, foremost in the \( \epsilon_1 \) direction, the cause of which is not fully understood.

Irrespective of the actual mechanism at work, we can effectively reduce the impact of the flux dependency by excluding the brightest stars when computing the PSF model. We found that rejecting the brightest 3 magnitudes below saturation level, corresponding roughly to \( \text{MAG\_AUTO} \in [15, 21.5] \), allows for very accurate PSF models as determined by the diagnostics in Equation 11 and exemplified in Figure 3, where we used the fainter star selection for the same field as in Figure A1. While there will be a slight misestimate of the effective PSF a galaxy at our faintest magnitudes of \( i \approx 24.5 \) would encounter, the change in flux and therefore in size compared to our fainter star selection is too small to be detectable by the diagnostics employed in this paper. As a practical consequence, we need to work with coadded images where the fainter stars can reliably be discriminated from galaxies.

APPENDIX B: TOLERANCES FOR PSF MODEL DIAGNOSTICS

In this section we seek to propagate failures of the PSF modeling approach in capturing both sizes and ellipticities of the actual PSF (and its spatial variation) into the the shear catalogs, thereby establishing limits on the required accuracy of the PSF models. We start with Eq. 13 from Paulin-Henriksson et al. (2008),

\[
\Delta \epsilon_{\text{sys}} \equiv (\epsilon_{\text{gal}} - \epsilon_s) \frac{\Delta x^2}{s_{\text{gal}}^2} = \frac{s_s}{s_{\text{gal}}} \Delta \epsilon,
\]

which estimates the systematic error in the shape of a deconvolved galaxy from the uncertainties in size and ellipticity of the PSF model, \( \Delta (x^2) \) and \( \Delta \epsilon \). Forming the correlation function yields

\[
\langle \Delta \epsilon_{\text{sys}} \Delta \epsilon \rangle = [\epsilon_s^2 + \langle \epsilon_s^2 \rangle] \left( \frac{\Delta x^2}{s_{\text{gal}}^2} \right) + \left( \frac{s_s}{s_{\text{gal}}} \right)^4 \langle \Delta \epsilon^* \Delta \epsilon \rangle
\]

\[+ \left( \frac{s_s}{s_{\text{gal}}} \right)^2 \langle \epsilon_s^* \epsilon_s \Delta \epsilon + \Delta \epsilon^* \epsilon_s \rangle.
\]

While the derivation strictly applies to moment-based measures only, and we seek to use it in a model-fitting context, the results depend weakly on the method used for shear estimation, provided the method yields an shape estimate that transforms as an ellipticity under an applied shear.
Now we will have to make several assumptions to relate the terms arising here to the PSF model diagnostics defined in Equation 9 and Equation 10. First, to pull out a common size-ratio for the first two terms, we need to assume that the size residuals do not correlate with stellar size:

$$\langle \Delta \epsilon_{\text{sys}}, \Delta \epsilon_{\text{sys}} \rangle = \left( \frac{\sigma_{\epsilon}^2}{s_{\text{gal}}} \right) \left[ \sigma^2_{\epsilon} + \langle \epsilon^2_{\epsilon} \rangle \right] \rho_3 + \rho_1 \left. \right| \left( \frac{\Delta s^2}{s_{\text{gal}}} \right) \langle \epsilon^2_{\epsilon} \Delta \epsilon + \Delta \epsilon^2_{\epsilon} \rangle.$$

(B3)

If we furthermore assume that $\Delta \epsilon$ and $\epsilon_{\epsilon}$ as well as $\Delta s^2$ and $\Delta \epsilon$ are uncorrelated, we can simplify the last term to

$$\left( \frac{\Delta s^2}{s_{\text{gal}}} \right) \langle \epsilon^2_{\epsilon} \Delta \epsilon + \Delta \epsilon^2_{\epsilon} \rangle.$$

(B4)

which allows us to identify it with $\rho_2$:

$$\langle \Delta \epsilon_{\text{sys}}, \Delta \epsilon_{\text{sys}} \rangle = \left( \frac{\sigma_{\epsilon}^2}{s_{\text{gal}}} \right) \left[ \sigma^2_{\epsilon} + \langle \epsilon^2_{\epsilon} \rangle \right] \rho_3 + \rho_1 \left. \right| \left( \frac{\Delta s^2}{s_{\text{gal}}} \right) \langle \epsilon^2_{\epsilon} \Delta \epsilon + \Delta \epsilon^2_{\epsilon} \rangle.$$

(B5)

We note that these additional assumptions are clearly problematic as one could easily imagine that residuals increase when the quantity that is modeled increases. For instance, both sizes and ellipticities tend to rapidly rise towards the field edges, where only a small number of stars can constrain the PSF model, a situation that should result in larger and correlated residuals for size and ellipticity.

Ideally, one would assess PSF model errors directly from Equation B2, which considers all possible correlation between sizes and ellipticities (and their errors). We leave this to a forthcoming investigation and want to highlight another immediate consequence of our derivation. If we accept the limitations laid out above resulting in Equation B5, we see that for $\rho_1$ a prefactor of order $10^{-2}$ and for $\rho_2$ of order $10^{-3}$ (for a reasonably well-fit PSF model) reduces their relative impact on the total shape error. In other words, if all diagnostic correlation functions were equal, $\rho_1$ is most demanding, followed by $\rho_2$ and then $\rho_2$. In practice, we find relatively larger size than ellipticity residuals, rendering $\rho_2$ a useful and, in the case of the flux-dependent PSF, even decisive diagnostic. On the other hand, due to its very small pre-factor, $\rho_2$ appears not to carry substantial information to assess the PSF model quality. We will therefore refrain from enforcing limits on $\rho_2$ and will assess the PSF models with $\rho_1$ and $\rho_3$ only.

The LHS of Equation B5 differs from the shear estimate only by the shear responsivity $P_\gamma$, which allows us to compare the total systematic budget with the statistical limit from the intrinsic shape scatter of the galaxies. For the two-point function, the number of galaxy pairs in a distance bin around $r$ is given by $n_{\text{gal}}(R_{\text{max}}^2 - R_{\text{min}}^2)$, with $R_{\text{min}}/R_{\text{max}}$ denoting the minimum and maximum radius of that bin. Assuming a Gaussian form of the intrinsic shape scatter with variance $\sigma^2_{\epsilon}$, we get

$$P_\gamma^{-2} \langle \Delta \epsilon_{\text{sys}}, \Delta \epsilon_{\text{sys}} \rangle < \frac{\sigma^2_{\epsilon}}{n_{\text{gal}}(R_{\text{max}}^2 - R_{\text{min}}^2)}.$$

(B6)

We still need an estimate for the pre-seeing size of galaxies $s_{\text{gal}}$ in our shape catalogs. For Gaussian-shaped galaxies and stars, one can directly relate the measurement of $\text{FWHM}_\text{RATIO}$ from $\text{m3shape}$ to the ratio of the moment-based size definition $s$ we have adopted in this paper:

$$\frac{s^2_{\text{gal}}}{s^2_{\epsilon}} = \text{FWHM}_\text{RATIO}^2 - 1.$$

(B7)

Together with the shear responsivity yields

$$T = P_\gamma \frac{s^2_{\text{gal}}}{s^2_{\epsilon}} = P_\gamma (\text{FWHM}_\text{RATIO}^2 - 1).$$

(B8)

Finally, requiring that no diagnostic function alone crosses the limit set by Equation B6, we get the set of tolerances in Equation 11.
