Using lattice simulations, we study the infrared behavior of a particularly interesting SU(2) gauge theory, with six massless Dirac fermions in the fundamental representation. We compute the running gauge coupling derived non-perturbatively from the Schrödinger functional of the theory, finding no evidence for an infrared fixed point up through gauge couplings $g^2$ of order 20. This implies that the theory either is governed in the infrared by a fixed point of considerable strength, unseen so far in non-supersymmetric gauge theories, or breaks its global chiral symmetries producing a large number of composite Nambu-Goldstone bosons relative to the number of underlying degrees of freedom. Thus either of these phases exhibits novel behavior.

Introduction  A new sector, described by a strongly interacting gauge theory, could play a key role in physics beyond the Standard Model. With the recent discovery of a 125 GeV Higgs-like scalar 1, 2, SU(2) vector-like gauge theories provide attractive candidates. Due to the pseudo reality of the fundamental representation of SU(2), two-color theories with $N_f$ massless Dirac fermions in this representation have an enhanced chiral symmetry, a novel symmetry breaking pattern $SU(2N_f) \to Sp(2N_f)$, and, therefore, a relatively large number of Nambu-Goldstone bosons (NGB) 3, 4. This feature has motivated SU(2)-based models of a composite Higgs boson 3, 5 and of dark matter 3, 5.

These models take $N_f = 2$, but new intriguing possibilities emerge for larger $N_f$. With $N_f$ just below the value at which asymptotic freedom is lost, a conformal window opens up, with the theory initially governed by a weakly-coupled infrared fixed point (IRFP). As $N_f$ is decreased, the strength of the fixed point increases. Below some critical value $N_f^c$, chiral symmetry is broken and the theory confines. This critical value defines the lower edge of the conformal window 10, 11. Knowing the extent of the window and the behavior of theories in it and near it could be crucial for building a successful model of BSM physics.

The extent of the conformal window is also interesting from a more theoretical point of view, and this is particularly true of the two-color theory. For example, a general notion about quantum field theories, as first applied to second-order phase transitions and critical phenomena, is that the renormalization group (RG) flow toward the infrared (IR) should result in a thinning of the degrees of freedom. This can provide an important constraint on IR behavior if it can be shown that the IR count cannot exceed the UV count. One implementation of this idea, much studied recently 12, 13, defines the degree-of-freedom count through the coefficient $a$ entering the trace of the energy momentum tensor on an appropriate space-time manifold. Although a UV-IR inequality can perhaps be proven, it does not seem to lead to useful constraints.

Another approach 14 defines the degree-of-freedom count via the thermodynamic free energy $F(T)$, using the temperature $T$ as the RG scale. The dimensionless quantity $f(T) \equiv 90 F(T) / \pi^2 T^4$ is $T$-independent for a free massless theory, leading to $f = 2 N_V + (7 / 2) N_F + N_S$, where $N_V$, $N_F$, and $N_S$ count the gauge, Dirac-fermion, and real-scalar fields. The conjectured inequality of Ref. 14 is that for an asymptotically free theory, $f_{IR} \equiv f(0) \leq f_{UV} \equiv f(\infty)$.

In the case of an IR phase with broken chiral symmetry and confinement, $f_{IR}$ counts the number of NGBs. For a vector-like SU(N) gauge theory with $N \geq 3$ and $N_f$ Dirac fermions, this count is $N_f^2 - 1$. Also, in the UV, $N_V = N_f^2 - 1$ and $N_F = N N_f$. The above inequality then demands $N_f^c < \frac{1}{4} \left( 7 N + \sqrt{81 N_f^2 - 16} \right)$. This is a testable constraint, and it has been satisfied by recent lattice simulations 15. For $N = 2$ on the other hand, the enhanced chiral symmetry, the different pattern of sym-
metry breaking, and the resultant enhanced NGB count $(2N_f^2 − N_f − 1)$ [3] lead to a significantly reduced bound on $N_f$ for the broken phase: $N_f^c < (4 + \sqrt{30})/2 \approx 4.7$.

Crude estimates of the edge of the conformal window, based on quasi-perturbative methods, also exist. Gap-equation methods [16] provide an estimate of the gauge coupling strength, and therefore maximum value of $N_f$, required to induce spontaneous chiral symmetry breaking. For any SU(N) gauge theory, these notions lead to the estimate $N_f^c \approx 4N$. While this is nicely compatible with the inequality for $N \geq 3$, it clearly disagrees with it for $N = 2$. This tension suggests that the $N_f = 6$ theory could be particularly worthy of study.

Early lattice calculations attempted to explore the two-color conformal window by studying the lattice theory at strong bare coupling [17, 18]. Recent efforts have primarily searched for an IRFP with non-perturbative running coupling calculations. Evidence that $N_f = 10$ ($N_f = 4$) is inside (outside) the conformal window is presented in Ref. [19]. Additionally, Ohki et al. argue that $N_f = 8$ is inside the conformal window [20]. The case $N_f = 6$, arguably the most interesting, while tackled by many groups [19, 21–24], has remained inconclusive.

Here we study the $N_f = 6$ theory, drawing on larger computational resources than in all previous work, to determine whether $N_f = 6$ has an IRFP by calculating the Schrödinger Functional (SF) [25] running coupling. We use the stout-smear [26] Wilson fermion action, which suppresses coupling the fermions to unphysical fluctuations of the gauge field on the scale of the lattice spacing. This improved action reduces lattice artifacts and allows us to search for an IRFP up through a large and interesting range of running couplings. Smearied actions have also been used in SF running coupling studies of other theories [27, 28].

**Preliminaries**

A stout-smearred fermion action replaces “thin” gauge links by “fat” links which are averaged with nearby gauge links. To define a stout-smearred Wilson link is we start with $C_\mu (x)$, the weighted sum of staples about the link $(x, x + \hat{\mu})$:

$$C_\mu (x) = \sum_{\nu \neq \mu} \rho_{\mu\nu} (U_{\nu}(x) U_\mu (x + \hat{\nu}) U_\nu^{-1} (x + \hat{\mu})) + U_\nu^{-1} (x - \hat{\nu}) U_\mu (x - \hat{\nu}) U_\nu (x - \hat{\nu} + \hat{\mu})$$.

(1)

We want our fat links to be elements of SU(N). This is guaranteed by taking the smearing kernel to be of form $\rho_{\mu\nu} = e^{iQ_{\mu\nu}(x)}$ with $Q$ an element of the Lie algebra su(N). We take

$$Q_\mu (x) = \frac{i}{2} \left( \Omega_\mu^\dagger (x) - \Omega_\mu (x) \right) - \frac{i}{2N} \text{Tr} \left( \Omega_\mu^\dagger (x) - \Omega_\mu (x) \right),$$

(2)

with $\Omega_\mu (x) = C_\mu (x) U_\mu^{-1} (x)$ ($\mu$ is not summed over). Then a fat link is defined by

$$U_\mu^{(n+1)} (x) = \exp \left( iQ_\mu^{(n)} (x) \right) U_\mu^{(n)} (x).$$

(3)

This smearing procedure may be applied iteratively, say $n_\rho$ times, to produce stout links $\tilde{U} = U^{(n_\rho)}$. It has the advantage that it is analytic and can therefore be used in conjunction with molecular dynamics (MD) updating schemes such as [29]. The formulas required to implement this smearing procedure in an MD algorithm are derived for the case of SU(3) links in [26]. We have derived the relevant formulas for the SU(2) case. Recently, another group implemented two-color stout-smearing as well [30].

We use only one level of stout-smearing with an isotropic smearing parameter $\rho_{\mu\nu} = \rho = 0.25$. As all calculations in this work are done with Dirichlet boundary conditions (BC) in the time directions, there is some ambiguity in how to implement the smearing of the gauge field near this boundary. We choose to not smear the boundary links with bulk links and vice versa. This choice results in a simpler running-coupling observable (which will be defined in the next section).

The Wilson fermion action contains an additional irrelevant operator that lifts the mass of the fermion doublers to the cutoff scale so they decouple from the calculation. This additional term explicitly breaks chiral symmetry, and as a result the fermion mass is additively renormalized. The bare mass $m_0$ therefore must be carefully tuned in order to restore chiral symmetry. The critical value of the bare mass (as a function of the bare coupling) $m_c (g_0^2)$ is defined as the bare mass value that results in a zero renormalized quark mass [31]. In practice, $m_c$ is determined, at fixed bare gauge coupling $g_0^2$ and lattice volume $(L/a)^3 \times 2L/a$, as the root of a fitted linear function to measurements of the renormalized quark mass versus the bare quark mass. This is done for a range of bare couplings and lattice volumes and the results are fit to a polynomial given by

$$m_c^\text{fit} \left( g_0^2, \frac{a}{L} \right) = \sum_{i=1}^{n} g_0^{-2i} \left[ a_i + b_i \left( \frac{a}{L} \right) \right].$$

(4)

Then, $m_c^\text{fit} (g_0^2, 0)$ is used in the running coupling calculations. All data used to fit $m_c^\text{fit} (g_0^2, a/L)$ and $m_c^\text{fit} (g_0^2, 0)$ are shown in Figure 1

In order to guarantee that we can take a continuum limit, we need to obtain data only from the weak-coupling side of any spurious lattice phase transition. With this in mind, we scan through the bare parameter space and locate peaks in the plaquette susceptibility on a $L/a = 10$ lattice. This search indicates a line in the $m_q - g_0^2$ plane of first order phase transitions that ends at a critical point at around $g_0^2 \approx 2.2$. For $g_0^2 \lesssim 2.2$, we see crossover behavior. In Figure 2 we show the above transition line plotted along with $m_c^\text{fit} (g_0^2, 0)$. Figure 2 indicates that our action has a sensible continuum limit only for $g_0^2 \lesssim 2.175$. Therefore, we examine the running coupling only on lattices with a bare coupling within this range.

**Running Coupling**

To define a non-perturbative renormalized coupling, we employ the Schrödinger
functional (SF) \([10]\). It is given by a path integral over gauge and fermion fields that reside within a four-dimensional Euclidean box of spatial extent \(L\) with periodic BC’s in spatial directions and Dirichlet BC’s in the time direction. We choose gauge BC’s \([32]\), \(U (x, k)|_{x^0=0} = \exp \left[-i\eta \frac{\pi}{\tau_3}\right]\) and \(U (x, k)|_{x^0=L} = \exp \left[-i (\pi - \eta) \frac{\pi}{\tau_3}\right]\), and fermion BC’s \([33]\), \(P_+ \psi|_{x^0=0} = \psi P_+|_{x^0=L} = \psi P_+|_{x^0=L} = 0\). These BC’s classically induce a constant chromoelectric background field whose strength is characterized by the dimensionless parameter \(\eta\). With these BC’s the SF is given by \(Z (\eta, L) = \int D[U, \psi, \bar{\psi}] e^{-S[U, \psi, \bar{\psi}]; \eta}\).

The running coupling is then defined by,

\[
\frac{k}{g^2 (g_0^2, \frac{L}{a})} = \frac{\partial}{\partial \eta} \log Z \bigg|_{\eta = \pi/4} = \left< \frac{\partial \Sigma}{\partial \eta} \right> (\Sigma = \Sigma (u), \bar{u}, sL), \tag{5}
\]

with \(k = -24 (L/a)^2 \sin \left[ (a/L)^2 (\pi/2) \right]\) so that the renormalized coupling agrees with the bare coupling at tree-level. The first two perturbative coefficients of the SF beta function are the universal coefficients given in \([10]\). This renormalization scheme has the virtue that it is fully non-perturbative and it is amenable to a lattice calculation.

We calculate the SF renormalized coupling over a range of bare couplings and lattice volumes. Lattice perturbation theory gives \(g_0^2 g^2\) as an expansion in powers of \(g_0^2\). This motivates an interpolating fit \([34]\).

\[
1 - \frac{1}{g_0^2} = \frac{1}{g^2 (g_0^2, \frac{L}{a})} = \sum_{i=0}^{N_{L/a}} a_{i, L/a} g_{2i}^2. \tag{6}
\]

We choose the lowest possible \(N_{L/a}\) to give a reasonable \(\chi^2\) per dof (in practice, values in the range \(\chi^2/\text{dof} \in [0.7, 1.5]\)), finding \(N_{L/a} \leq 12 = 6\) and \(N_{L/a} > 12 = 5\). This procedure produces smooth functions, one for each lattice volume \(L/a\), of the renormalized coupling versus the bare coupling. Before using this interpolation for further analysis, it is worth noting that there is no hint of an IRFP in the lattice data and therefore in the interpolating curves. At any fixed \(g_0^2\), the running coupling \(g^2 (g_0^2, \frac{L}{a})\) is seen only to increase as a function of \(L/a\) in the range of the data.

The question is whether a careful continuum extrapolation will indicate otherwise. A step scaling \([35]\) analysis allows us to address this issue and to study the renormalized coupling over a large range of scales in computationally feasible manner. The continuum step scaling function \(\sigma (u, s)\) is defined by

\[
\int_u^{\sigma(u, s)} \frac{dg^2}{\beta (g^2)} = 2 \log s. \tag{7}
\]

It is the renormalized coupling at a length scale \(sL\) given that the running coupling \(g^2 = u\) at a length scale \(L\). On the lattice we calculate the discrete step scaling function,

\[
\Sigma (u, \frac{a}{L}, s) \equiv \frac{g^2 (g_0^2, \frac{L}{a})}{g^2 (g_0^2, \frac{L}{a})} \bigg|_{g^2 (g_0^2, \frac{L}{a}) = u}. \tag{8}
\]

It is the value of the renormalized coupling on a lattice volume of \((sL/a)^4\) and bare coupling tuned such that we have a renormalized coupling of \(u\) on a lattice of volume \((L/a)^4\). We arrive back at a continuum step scaling function by taking the continuum limit:

\[
\sigma (u, s) = \lim_{a/L \to 0} \Sigma (u, \frac{a}{L}, s). \tag{9}
\]

From here we use \(s = 2\) and drop reference to this from our notation.

To extract \(\sigma\) as a function of \(u\), we first use the interpolating fits, given by Eq. \(6\) to evaluate \(\Sigma\) at each fixed value of \(u\) and \(L/a = 5, 6, 7, 8, 9, 10, \) and \(12\). We take the continuum limit, at each \(u\) independently, by fitting \(\Sigma (u, a/L)\) to a polynomial in \(a/L\), and extrapolating to \(a/L \to 0\). Our result, shown in Fig 2, displays several plots of the quantity \((\sigma (u) - u) / u\) versus \(u\). This quantity is a finite-difference version of the continuum beta function. In one curve (red), we fit \(\Sigma (u, a/L \leq 1/6)\) to a quadratic polynomial and then extrapolate the result to \(a/L \to 0\). Additionally, we show, \(\Sigma (u, a/L \leq 1/5)\) extrapolated from a cubic polynomial fit (green). We see that these two curves are consistent, but the errors of the cubic extrapolation become large at \(u \approx 8\). The remaining (blue) curve is obtained with a constant extrapolation to the continuum using only the three points with \(a/L \leq 1/9\).

To assess the goodness-of-fit of any particular functional form for continuum extrapolation of \(\Sigma\) we examine \(\chi^2/\text{dof}\) over the entire range of \(u\). For the constant extrapolation (blue) in Fig. 2 for \(L/a \geq 9\), \(\chi^2/\text{dof}\) varies from 0.5-2.
A quadratic extrapolation (red) for $L/a \geq 6$ and a cubic extrapolation for $L/a \geq 5$ have comparable $\chi^2/\text{dof}$ ranging from 0.5-4 throughout the range of $u$. The constant (quadratic and cubic) extrapolation relies on fits with two (three) degrees-of-freedom.

These various extrapolations all perform well at reproducing the perturbative two-loop curve (magenta) at small values of $u$. If the resulting curves were to cross zero at some larger $u$, this would be indicative of an IRFP. We see no indication of this; in fact we see, regardless of which extrapolation we use, the running coupling grows up to and beyond our input coupling strength. This indicates that the quadratic and cubic fits extrapolate to a value of $\bar{g}^2$ that is well above the smallest-$\sigma$ points. It is likely that the quadratic and cubic fits extrapolate to a value of $\sigma$ that is well above the smallest-$a/L$ points. It is also evident that the quadratic and cubic fits extrapolate to a value of $\sigma$ for $u \lesssim 7$. It is also clear that the quadratic and cubic fits extrapolate to a value of $\sigma$ for $u \lesssim 7$. It is also evident that the quadratic and cubic fits extrapolate to a value of $\sigma$ that is well above the smallest-$a/L$ points. It is likely that the true extrapolated value is somewhere between the constant and quadratic extrapolations.

Recently Hayakawa et al. claim to see evidence of an IRFP in the two-color six-flavor theory [24]. They employ the SF method as we do but with the unimproved Wilson fermion action and a linear extrapolation to the continuum. It is reasonable to expect that for large enough $L/a$ the linear term will be the dominant lattice artifact but it is difficult to quantify how large an $L/a$ is necessary outside of perturbation theory. Other extrapolation forms, including...
quadratic terms can be used to fit their data with a comparable or slightly better $\chi^2$/dof. When this is done, we cannot conclude that an IRFP exists. Moreover, from our data set, sampling many more bare couplings and lattice volumes, we are able to study the relative contributions of different lattice artifacts. In Figure 3, we see that in the strong coupling regime, the quadratic term becomes significant in the $a/L$ range studied by Hayakawa et al. and by us. With the caveat that we use a different lattice action, the relative importance of the quadratic term suggests that concluding the existence of an IRFP from a linear extrapolation to the continuum is premature.

To summarize, for an SU(2) gauge theory with six massless fermions in the fundamental representation, we find no evidence of an infrared fixed point in the running gauge coupling as defined in the Schrödinger Functional scheme. Our simulations reach well into a strong-coupling range, potentially capable of triggering chiral symmetry breaking and confinement. We conclude that this theory either flows to a very strong infrared fixed point, so far unseen in non-supersymmetric theories, or it breaks chiral symmetry and confines, producing a large number (65) of Nambu-Goldstone bosons, well above the number of underlying fermionic and gauge degrees of freedom. Thus either of these (zero-temperature) phases exhibit novel behavior. In the latter case, the finite-temperature phase transition can be expected to have interesting features. We could in principle probe even larger couplings than presented here, but the computational challenges and lattice-artifact difficulties grow with coupling strength. Other approaches, such as the computation of correlation functions and the particle spectrum, will be important to firmly establish the infrared nature of this theory.

Acknowledgments We thank Robert Shrock for helpful discussions. We would like to acknowledge our use of the Chroma software package for all calculations performed here.
