Painless gouty tophus in the nasal bridge
A case report and literature review

Shih-Lung Chen, MD\textsuperscript{a,b}, Jim-Ray Chen, MD\textsuperscript{b,c}, Shih-Wei Yang, MD MSc\textsuperscript{b,d,*}

**Abstract**

**Rationale:** A gouty tophus, arising from the deposition of monosodium urate crystals (MSU), rarely occurs in the nasal bridge. There have been only 7 documented cases of a gouty tophus in the nasal bridge from 1978 to 2018 in English-language literature.

**Patient concerns:** A 65-year-old male had a chief complaint of a lump in the nasal bridge that was slowly growing for over 1 year.

**Diagnosis:** MSU crystals were confirmed through ultrasonography (US) and pathological examinations.

**Interventions:** A cosmetically less destructive method, ultrasound-guided fine needle aspiration cytology (FNAC) was used to approach the mass lesion of nasal bridge.

**Outcomes:** The diagnosis was confirmed as a gouty tophus without performing a nasal subdermal exploration.

**Lessons:** This case report is the first use of US with FNAC to approach and diagnosed a gouty tophus in the nasal bridge.

**Abbreviation:** CT = computed tomography, FNAC = fine needle aspiration cytology, MSU = Monosodium urate, PAP = Papanicolaou, US = ultrasonography.

**Keywords:** fine needle aspiration cytology, gouty tophus, nasal bridge, ultrasonography.

1. Introduction

The prevalence of gout is rising in the modern world. In Taiwanese society, the incidence of gouty arthritis is approximately 4.92%.\textsuperscript{[1]} Gout attacks primarily involves a single joint of the lower extremities, especially the first metatarsophalangeal joint.\textsuperscript{[2]} Other frequent sites include the knees, ankles, and elbows. It is uncommon that a gouty tophus occurs in the region of the head and neck. There have been only 7 documented cases of a gouty tophus in the nasal bridge from 1978 to 2018 in English-language literature.

In this study, we report a patient who presented with a nonpainful, slowly progressive, enlarged mass in the nasal bridge. We successfully used a cosmetically less destructive method, ultrasound-guided fine needle aspiration cytology (FNAC), to approach the mass lesion, and the diagnosis was confirmed as a gouty tophus without performing a nasal subdermal exploration.

This was a rare case, as a tophus in the nasal bridge is a rare occurrence, and here, we report the first use of ultrasonography (US) with FNAC to approach the nasal bridge mass.

2. Case report

A 65-year-old male came to our department with a chief complaint of a lump in the nasal bridge that was slowly growing for over 1 year. The patient reported no epistaxis, rhinorrhea, nasal obstruction, traumatic episode, surgical history, or painful sensation. This patient had been treated for the underlying diseases of gouty arthritis, which were under regular Colchicine and Febuxostat control for 5 years. The physical examination demonstrated a fixed and hard mass in the central third nasal bridge (Fig. 1). The fiberoptic nasopharyngoscopy demonstrated nasal septal deviation to the right, but no mass or mucosal lesion was detected in the bilateral nasal cavities. The laboratory data revealed a normal C-reactive protein level (1.63 mg/L; normal: 0–10 mg/L) but with hyperuricemia (9.1 mg/dL; normal: 2.4–6.8 mg/dL). A head and neck computed tomography (CT) scan without contrast displayed one radiopaque mass protruding and crossing over the nasal bridge (Fig. 2). On the bone windows CT, the mass lesion invaded into the nasal bone and the septal cartilage. To differentiate this mass lesion, we arranged ultrasound-guided FNAC. The target US revealed an isoechoic soft tissue-like mass surrounding the nose bridge, sized of 19.9 mm in diameter and 6.6 mm in thickness (Fig. 3). There were a few internal hyperechoic foci, but no definite intrinsic flows appeared on the Doppler scan of the mass. FNAC was performed from the site using a 21-gauge needle. White particulate substance was obtained. Papanicolaou (PAP)-stained smears demonstrated a background of necrotic debris with clusters of amorphous materials, macrophages, and occasional multinucleated giant cells. Thin needle-shaped crystals in stacks (Fig. 4A) were distributed in the smears. Under direct polarized...
light, they presented high brightness against the black background with negative birefringence (Fig. 4B). Monosodium urate (MSU) crystals were confirmed.

The patient refused the advanced surgical excision of the nasal tophus, requesting medical treatment alone. The rheumatologist adjusted the doses of Colchicine and Febuxostat. The serum urate level has remained below 4.5 mg/dL over the entire 6 months of follow-up. No gout attack has been noted, and the lump has not progressed in size.

3. Ethical approval
Written informed consent was obtained from the patient for publication and any associated images. Approval of this case
study was obtained from the Institutional Review Board of Chang Gung medical foundation (IRB No.201800958B0).

4. Discussion

A gouty tophus is composed of MSU crystals. A tophus can deposit in various sites within the human body, which can be divided into typical or atypical locations. A tophus in the head and neck region is classified as atypical and is rare in the nasal bridge.

A tophus can cause lytic changes in the peripheral structures and painful sensation. The region of the nasal bridge is innervated by the anterior ethmoidal nerve and the infraorbital nerve. During surgery of the nasal bone fracture, these nerves can be blocked for anesthesia and pain relief. Pain along with redness, warmth, swelling development in deposition of MSU is mediated by inflammatory substances that are produced after cell injury. The most important of pain-inducing molecules contains prostaglandins, bradykinin, cytokines, and substance P.

It is unknown why the tophus in the nasal bridge was painless in the presented case despite the underlying nasal bone being eroded. We reviewed all case reports regarding a tophus of the nasal bridge in English-language literature, and the painless characteristic was often described (Table 1). Nevertheless, other types of pathology within the nasal bridge could contribute to a painful sensation.

A nasal tophus is strongly associated with gouty arthritis. In the previous 7 case reports regarding the tophi of the nasal bridge, only one article mentioned that their patient had no history of gouty arthritis, and the nasal tophus was even the initial presentation of gout. Others revealed the history of gouty arthritis persisting for years, even under medical control.

Probenecid was prescribed in one report. In addition, 2 reports employed Allopurinol to control gout. Our patient differed from earlier patients. He received Cocaine and Febuxostat to control his gout.

MSU crystal formation reflects excessive levels of blood urate. Hyperuricemia is defined as a serum urate level above the MSU saturation point (> 6.8mg/dL), at which point the risk of crystallization increases. Lin et al stated that the incidence of gout increased as the serum urate level rose. Although hyperuricemia is essential for MSU crystal formation, only 2 to 36% of hyperuricemic patients in fact develop gout. The mechanism of MSU formation is complex, being affected by environmental factors such as cold temperature, acidity, and physical perturbation. However, whether biomedical factors such as albumin, antibodies, and immunoglobulins promote MSU formation remains controversial. Further, a tophus is a feature of advanced gout; a tophus contains a nest of MSU crystals surrounded by soft tissue and inflammatory cells that are microscopically evident. Extracellular trapping of crystals by

CT = computed tomography, FNAC = fine needle aspiration cytology, N/A = data not available, US = ultrasonography.
neutrophils contribute to tophus formation. A tophus contains 3 primary zones: a central core of MSU crystals; a surrounding, high-density, cellular coronal zone; and an outer fibrovascular zone. Both of the coronal and fibrovascular zones contain many macrophages and plasma cells, fewer mast cells, and scattered T and B lymphocytes.\textsuperscript{117}

We performed US and FNAC to approach the mass lesion in the nasal bridge. US is noninvasive and useful to detect MSU crystals over articular cartilages.\textsuperscript{118} Some distinctive characteristics of gout under US include being hypoechoic to hyperechoic, with an inhomogeneous appearance, frequently surrounded by a small anechoic rim.\textsuperscript{119} Our sonographic images showed an inhomogeneous appearance with certain internal hyperechoic foci but no internal flow, which is compatible with the characteristics of tophi under US (Fig. 3).

FNAC is an alternative option for a minimally invasive procedure and diagnostic test to verify the tophus in the nasal bridge. The PAP stain and the polarized light of microscopy can confirm the diagnosis of gouty tophus.\textsuperscript{120} PAP-stained smears of gout display a granular amorphous substance and slim needle-shaped crystals in groups. Under the polarized light of microscopy, the MSU crystals would be negative birefringence.\textsuperscript{121} Our cytological findings were consistent with these findings and verified the diagnosis of gouty tophus (Fig. 4). Currently, dual energy CT-scan can be used as another diagnostic option for detection of MSU deposits.\textsuperscript{122}

Wu et al. stated the patients with nasal tophi in the literature are more likely to be male and middle aged.\textsuperscript{112} Our finding was in accordance with theirs (Table 1). They concluded that surgery was indicated for cosmetic purposes or recalcitrant symptoms, such as nasal obstruction or difficulty breathing.\textsuperscript{112} However, the aesthetic appearance appeared not to concern our patient, and there was no reported discomfort except for the convex lump on the nasal bridge. Consequently, after cytological diagnosis demonstrated a benign lesion, the patient did not request further surgical excision and elected to take adjusted doses of Cochine and Febuxostat. The lump remained stable, and the serum urate was kept below 4.5 mg/dL over the following 6 months. Two prior reports mentioned that, after surgery, the local tophus did not recur over follow-up periods of 6 months and 2 years, respectively.\textsuperscript{11,12}

In the previous case reports, surgical excision was conducted after the head and neck CT scan was performed. Three case reports described the surgical procedures in detail. Hughes et al.\textsuperscript{8} used intranasal transfixion and inter-cartilaginous incision with the endoscopic approach to remove the tophus. Kwak et al.\textsuperscript{10} created an external, inverted-V-shaped incision along the columella and dissected the subperichondrial plane to remove the tophus. The harvested septal cartilage was placed along the columella and dissected the subperichondrial plane to respectively.\textsuperscript{8,12} They concluded that surgery would likely lead to scar formation and possibly the alteration of facial cosmetic outlooks. However, through the FNAC approach, the facial contour was not destructed. The diagnosis can be achieved before the decision of definite treatment is made. Therefore, we consider US with FNAC to be a promising tool to approach and diagnose a facial mass without substantial surgical destruction.

5. Conclusion
We demonstrated a gouty tophus in the nasal bridge, presenting as a hard and fixed mass, leading to the erosion of the nasal bone and the septal cartilage. The painless presentation and strong correlation with the gouty arthritis are the distinguishing features. The use of US and FNAC to approach the tophus in the nasal bridge is promising for the diagnosis and is not as destructive as surgery. We suggest that US with FNAC should be considered as a tool for evaluating a facial mass before a definite treatment modality is chosen. Although very rare, a gouty tophus should be considered in the differential diagnosis of a nasal bridge lump and can be successfully diagnosed by US with FNAC.
