R. China, 6South China Collaborative Innovation Center for Poultry Disease Control and Product Safety, Guangzhou, 510642, P. R. China.

The group of avian sarcoma and leukemia virus (ASLV) in chickens contains six highly related subgroups, A to E and J. Four genetic loci, tva, tvb, tvc and tvj, encode for corresponding receptors that determine the susceptibility to the ASLV subgroups. The prevalence of ASLV in hosts may have imposed strong selection pressure toward resistance to ASLV infection, and the resistant alleles in all four receptor genes have been identified. In this study, two new alleles of the tva receptor gene, tva5 and tva6, with similar intronic deletions were identified in Chinese commercial broilers. These natural mutations delete the deduced branch point signal within the first intron, disrupting mRNA splicing of the tva receptor gene and leading to the retention of intron 1 and introduction of premature TGA stop codons in both the longer and shorter tva isoforms. As a result, decreased susceptibility to subgroup A ASLV in vitro and in vivo was observed in the subsequent analysis. In addition, we identified two groups of heterozygous allele pairs which exhibited quantitative differences in host susceptibility to ASLV-A. This study demonstrated that defective splicing of the tva receptor gene can confer genetic resistance to ASLV subgroup A in the host.

Entry of retroviruses into the host cell represents one of the most important steps in the viral life cycle1. The process is mediated by the interaction of retroviral envelope glycoproteins with specific cell surface receptors2. This interaction, as well as subsequent phases of virus entry, requires a perfect match of envelope glycoproteins and receptors3,4. Despite the strict structural requirements for these interactions, hypervariability of retroviral glycoproteins can change the receptor usage and broaden the host range. Avian sarcoma and leukemia viruses (ASLVs) in chickens are a closely related group of retroviruses thought to have evolved from a common viral ancestor into six subgroups, A to E and J, which utilize four different cell surface receptors encoded by four genetic loci, tva, tvb, tvc and tvj5-6. The susceptibility of chicken cells to subgroup A ASLV is determined by the tva locus, which encodes a protein belonging to the family of low-density lipoprotein receptors7. The susceptibility to the subgroup B, D and E ASLVs are determined by the tvb locus, which encodes the tumor necrosis factor receptor-related protein8-10. The Tvc protein encoded by the tvc locus, closely related to the mammalian butyrophilins, serves as the receptor for subgroup C ASLV11. The receptor for subgroup J ASLV was identified as chicken Na+/H+ exchanger type 1 (chNHE1), encoded by the tvj locus12.

The complete resistance or decreased susceptibility of host cells to a particular ASLV subgroup can be caused by genetic variations of the tva, tvb, tvc or tvj locus, resulting in the complete lack of receptor protein expression or the expression of an aberrant protein not suitable as a viral receptor. Genetic variations that confer host resistance to infection by specific ASLVs, tvra, tvb, tvrb and tvrc alleles, have been identified in some inbred lines of White Leghorn chickens. The mutations found in the resistant alleles result in premature termination or a frameshift in the receptor-encoding loci13,14, decreased receptor expression and display15, and even single amino acid substitutions in the receptor gene sequence13,15. In addition, the absence of tryptophan 38 of the cell surface receptor
abrogates binding of the subgroup J envelope glycoprotein to ASLV-J-resistant cells, which discriminates sensitive from resistant avian species.

Although research on host genetic resistance to specific ASLVs has progressed in recent years, the current status of host resistance to infection by specific ASLVs in Chinese chickens is unknown. In order to identify additional resistance alleles of the \( tva \) receptor gene, we screened a panel of Chinese commercial broiler lines, which have undergone strict virus eradication management. Here, we characterized two alleles of the \( tva \) receptor gene, named \( tva^s \) and \( tva^a \), respectively, with similar intronic deletions encompassing the deduced branch point signal within the first intron and leading to defective splicing of \( tva \) mRNA. We also identified two groups of heterozygous allele pairs which exhibited discrepant susceptibility to subgroup A ASLV. To our knowledge, this study is the first to report genetic variations within the \( tva \) receptor gene that result in a quantitative effect on ASLV-A susceptibility and pathogenesis in Chinese chickens.

**Results**

**Polymorphisms in the first intron of \( tva \) receptor gene and genotyping.** To dissect genetic variations within the \( tva \) receptor gene in a panel of Chinese commercial broiler lines, the genomic region of the \( tva \) gene in each bird was amplified and sequenced. Four novel variants in the same region within the first intron of the \( tva \) gene were identified in the Chinese chickens surveyed. In addition to the \( tva^s \) and \( tva^a \) alleles\(^{14}\), sequencing revealed one new variant with a deletion of the sequence CGCTCACCCC (nucleotides 502 to 511) and another new variant with a deletion of the sequence CGCTCACCCGCCCCC (nucleotides 502 to 516) (Fig. 1). We designated these two novel variants as \( tva^{mut502} \) and \( tva^{mut516} \), respectively. The deduced branch point signal within the first intron and leading to defective splicing of the \( tva \) mRNA. The underlined sequences indicate the putative alternative branch point signals. The intron-exon junctions are indicated by vertical bars, while exon sequences are indicated in italics. The nucleotide numbering based on the published \( tva \) allele genomic sequence (GenBank accession number: AY531262.1) is provided for reference.

**Identification of novel \( tva \) receptor gene splicing variants.** Sequencing revealed that both the \( tva^s \) and \( tva^a \) alleles delete the CTACAC consensus sequence of the branch point signal\(^{17} \) (Fig. 1). These deletions include the A nucleotide, which is required for the first cleavage-ligation step of the splicing reaction\(^{18} \). Therefore, we hypothesized that the deletion mutations may disrupt splicing of the \( tva \) precursor mRNA (pre-mRNA) (Fig. 2A).

To determine whether these specific mutations would interfere with the process of \( tva \) pre-mRNA splicing, the full-length \( tva \) coding sequence from lives samples of defined origin and from DF-1 cells as a control were amplified by RT-PCR using primers crossing the entire coding sequence of the \( tva \) receptor gene (Fig. 2B). The cDNA products from the DF-1 cells and \( tva^a \) samples from lives were of the expected sizes corresponding to the longer and shorter \( tva \) isoforms.\(^{12} \) However, the cDNA products from the \( tva^{mut502} \) and \( tva^{mut516} \) homozygous samples, as well as those from the \( tva^{mut502} \), \( tva^{mut516} \), \( tva^{mut502} \), \( tva^{mut516} \) and \( tva^{mut502} \) heterozygous samples, were longer by approximately 200 bp (Fig. 2C), similar to those of the \( tva^{mut502} \) and \( tva^{mut516} \) homozygous samples\(^{14} \). These longer sequences suggest that the first intron is retained (i.e., nucleotides 337 to 530, based on the published \( tva \) allele genomic sequence, GenBank accession number: AY531262.1). Interestingly, the products from \( tva^{mut502} \), \( tva^{mut516} \), \( tva^{mut502} \) and \( tva^{mut516} \) heterogeneous samples from lives by RT-PCR have three transcripts. Except for one transcript was the same with the normal shorter \( tva \) isoforms, the another two transcripts were longer by approximately 200 bp compared to those of the longer and shorter \( tva \) isoforms, respectively (Fig. 2C).

In order to verify the retention of intron 1 in the transcripts of the \( tva^s \) and \( tva^a \) alleles, as well as to identify the heterozygotes, their RT-PCR products were then cloned into the T-vector for sequencing. Separate sequence analysis of PCR products revealed that the retention of the first intron in the RT-PCR products and a deletion of the corresponding sequence (CGCTCACCCC or CGCTCACCCGCCCCC) within the first intron in both the longer and shorter \( tva \) isoforms of \( tva^{mut502} \) and \( tva^{mut516} \) homozygotes, as well as the group of heterozygotes included \( tva^{mut502} \), \( tva^{mut516} \), \( tva^{mut502} \), \( tva^{mut516} \), \( tva^{mut502} \) and \( tva^{mut516} \) (Fig. 2D). Although these similar sequencing events of the branch point with corresponding deletions in the \( tva^a \) isoforms, the another two isoforms, respectively (Fig. 2C).

1 $tva^{502–516}$ = multiple allele of tvr502, tvr515, tvr516 and tvr517 at the tvr locus.
2 tvr502–516 = susceptible homozygote of tvr receptor gene, tvr513 = heterozygote of deleted ACCCCGCCC, tvr514 = heterozygote of deleted ACCCC, tvr515 = heterozygote of deleted CGCTCACCCC; tvr516 = heterozygote of deleted CEFs to subgroup A ASLV, and the results were consistent with those reported by Reinis et al. (date not shown).

Reduced susceptibility of Chinese chickens to subgroup A ASLV.

Since two independent intronic deletions that resulted in defective splicing of tvr mRNA were identified, we hypothesized that these deletion mutations may confer their functional significance. To determine the effects of tvr502–516 and tvr515–516 alleles, as well as their heterozygous variants, on subgroup A ASLV susceptibility, CEFs of defined origin were infected with the RCASBP(A)-EGFP reporter virus, a replication-competent ASLV vector encoding EGFP, and the time course of infection was followed by quantitating the percentage of green fluorescent cells by flow cytometry over 7 subsequent days. DF-1 cells (tvr515) are susceptible to subgroup A ASLV and thus were used as a positive control. As expected, the DF-1 cells were efficiently infected by RCASBP(A)-EGFP, with more than 60% of the cells being infected on day 1 post-infection, and virtually complete infection of cells was achieved by day 3 (Fig. 4A). However, a very different result was observed when the tvr502–516 and tvr515–516 CEFS were infected with RCASBP(A)-EGFP. Both the tvr502–516 and tvr515–516 CEFS were much less efficiently infected with RCASBP(A)-EGFP, with only 2.0% and 1.0% of the cells infected on day 1, respectively, and the virus spread very slowly, with only 19.8% and 20.5% of the cells infected by day 7, respectively (Fig. 4C). We also determined the susceptibility of tvr515–516 and tvr515–516 CEFS to subgroup A ASLV, and the results were consistent with those reported by Reinisová et al. (date not shown). In a separate experiment, quantitative differences in host susceptibility to ASLV-A were observed between heterozygotes.
Figure 2 | Deletion of internal intron 1 sequences affects splicing of tva receptor gene. (A) Schematic diagram of intron 1 in tva pre-mRNA showing the 5' splice site, 3' splice site and the branch point sequence (corresponding bases are indicated by dots). The adenosine residue which is required for the first cleavage-ligation step of the splicing reaction is marked by an arrow. (B) Schematic diagram of RT-PCR strategy. The use of PCR primers TVA3 and TVA4 generated easily discernible whole cDNA fragments that were amplified from the longer and shorter tva forms, respectively, as well as the longer and shorter tva forms with intron 1 retention. Sizes of diagnostic PCR products are indicated. Exons are drawn as boxes, retained introns are shown as black lines and spliced introns as diagonal lines. The vertical white bar indicates the position of the intronic deletion. (C) RT-PCR of RNA isolated from DF-1 cells and samples from lives of defined origin. Lane 1–16 indicated the RT-PCR products from DF-1 cells and the tva heterozygotes, while splicing of longer and shorter tva forms of tva homozygotes containing intron 1 with the corresponding deletion mutation, however, the tva heterozygotes generate both the normal splicing of shorter tva forms and abnormal splicing of longer and shorter tva forms. Stars represent premature TGA stop codons identified in the alternative transcript.
which could be classified into two groups. The \textit{tva}^{a/s} and \textit{tva}^{a/r6} CEFs were efficiently infected with RCASBP(A)-EGFP at a similar rate to that of DF-1 cells (\textit{tva}^{a/s}) (Fig. 4B), with 94.3% and 95.8% of the cells infected by day 7, respectively (Fig. 4C). However, the \textit{tva}^{a/r4}, \textit{tva}^{a/r5} and \textit{tva}^{a/r6} CEFs were inefficiently infected by RCASBP(A)-EGFP (Fig. 3B), with only 27.0%, 34.6% and 18.4% of the cells being infected at 7 days post-infection, respectively (Fig. 4C). These results clearly indicated the inefficient infection and slow spread of the subgroup A ASLV in the \textit{tva}^{a/s} and \textit{tva}^{a/r6} homozygous CEFs and the \textit{tva}^{a/r4}, \textit{tva}^{a/r5} and \textit{tva}^{a/r6} heterozygous CEFs.

**Inefficient infection of chinese chickens by subgroup A ALV.** In order to further determine the \textit{in vivo} effects of the \textit{tva}^a and \textit{tva}^s alleles, as well as their heterozygous variants, commercial broilers randomly collected from lines 208, 419, 502 and 603 were inoculated with subgroup A ALV, and blood samples of chicks were tested for ALV-A infection. One-day-old chicks were inoculated with 0.2 mL of subgroup A ALV (2.4 S/P) into the abdominal cavity, and inoculated once again when they were 5 days old. At one month post-infection, the status of ALV-A infection was determined by RT-PCR of RNA extracted from whole blood samples. As expected, the \textit{tva}^s birds were all positive for ALV-A. While the \textit{tva}^{a/r4}, \textit{tva}^{a/r5} and \textit{tva}^{a/r6} birds were nearly all positive for ALV-A, in the cohort of 9, 5, 9 and 5 of the \textit{tva}^{a/r4}, \textit{tva}^{a/r5} and \textit{tva}^{a/r6} chicks, respectively, all birds were positive for ALV-A, except for one \textit{tva}^{a/r5} bird (Table 2). However, the susceptibility to subgroup A ALV of the homozygous \textit{tva}^{a/r4}, \textit{tva}^{a/r5} and \textit{tva}^{a/r6} and the heterozygous \textit{tva}^{a/r4}, \textit{tva}^{a/r5} and \textit{tva}^{a/r6} birds decreased. In the cohort of 32, 18, 15, 11, 6, 9, 5, 8, 6 and 17 of the \textit{tva}^{a/r4}, \textit{tva}^{a/r5}, \textit{tva}^{a/r6}, \textit{tva}^{a/r4}, \textit{tva}^{a/r5}, \textit{tva}^{a/r6}, \textit{tva}^{a/r4}, \textit{tva}^{a/r5} and \textit{tva}^{a/r6} chicks, only 4, 1, 1 and 1 and 1 of the \textit{tva}^{a/r4}, \textit{tva}^{a/r5}, \textit{tva}^{a/r6} and \textit{tva}^{a/r6} chicks were positive for ALV-A (Table 2). These results were consistent with those of the \textit{in vitro} experiment.

Taken together, these results clearly demonstrated that the deletion of the branch point signal within the first \textit{tva} intron disrupt mRNA splicing of the \textit{tva} receptor gene, which explains the decreased susceptibility of the homozygous \textit{tva}^{a/r4} and \textit{tva}^{a/r6} birds and the heterozygous \textit{tva}^{a/r4}, \textit{tva}^{a/r5}, \textit{tva}^{a/r6}, \textit{tva}^{a/r4} and \textit{tva}^{a/r6} birds to infection by subgroup A ASLV.

**Discussion**

In the present study, we described the identification of two similar intronic deletions encompassing the deduced branch point signal in the \textit{tva} receptor gene, which were shown to significantly decrease the susceptibility of chickens to infection by ASLV-A. Furthermore, we identified two groups of heterozygotes based on their quantitative differences in host susceptibility to ASLV-A. This study is the first to report genetic defects in the \textit{tva} receptor gene that account for a quantitative effect on ASLV-A susceptibility and pathogenesis in Chinese chickens. The altered susceptibility to infection by ASLV-A was observed both in cultured cells and in chicks challenged with subgroup A ALV.

Alternative splicing allows individual genes to produce two or more variant mRNAs, which in many cases encode functionally distinct proteins.\textsuperscript{19,22–23} Indeed, two \textit{tva} receptor gene splicing variants created by alternative splicing were identified previously\textsuperscript{19,24}. Binding of more than one receptor, probably two, is needed for entry of virions via the Tva800 receptor that is encoded by the shorter \textit{tva} forms, whereas binding of just one Tva950 receptor encoded by the longer \textit{tva} forms is sufficient for successful entry\textsuperscript{25}. Alternative splicing can be modulated by variation both in the \textit{cis} genomic splicing signals and in the cellular pathways that regulate splicing\textsuperscript{12,26–27}. In this study, we identified the alternative splicing of the \textit{tva}^a and \textit{tva}^s resistant alleles resulting from intronic deletions encompassing the deduced branch point signal, leading to the retention of the first intron and introduction of premature TGA stop codons in the longer and shorter \textit{tva} forms (Fig. 2). Alternative splicing events generally create a premature termination codon that would cause the resulting...
mRNA to be degraded by nonsense-mediated mRNA decay\(^{28-29}\). Therefore, alternative splicing of mRNAs that changes the encoded proteins has profound functional effects\(^{23,30-31}\). Experimental analysis of distinct protein isoforms showed that alternative splicing regulates binding between proteins, between proteins and nucleic acids, as well as between proteins and membranes\(^{23,31-33}\). In most cases, the binding

\(^{1}\) tva\(^{502-516}\) = multiple allele of tva\(^{s}\), tva\(^{r}\) and tva\(^{a}\) at the tva locus.

\(^{2}\) tva\(^{s}\) = susceptible homozygote of tva receptor gene, tva\(^{s/r}\) = heterozygote of deleted ACCCCGCCCCC, tva\(^{s/r}\) = heterozygote of deleted ACCTCACCCCC; tva\(^{r}\) = heterozygote of deleted CGCTCACCCCC; tva\(^{r/r}\) = heterozygote of deleted CGCTCACCCCC; tva\(^{3/6}\) = heterozygote of deleted ACCCCGCCCCC and CGCTCACCCCC; tva\(^{5/6}\) = heterozygote of deleted ACCCCGCCCCC, CGCTCACCCCC and tva\(^{5/6}\) = heterozygote of deleted ACCCCGCCCCC.
affinity is modulated, but the binding is not abolished completely. The tva<sup>r</sup> and tva<sup>a</sup> alleles harbor an intronic deletion of the branch point and disrupt splicing of the tva receptor gene, leading to decreasing binding affinity between the Tva receptor and envelope glycoproteins of ASLV-A and display of the Tva receptor on the cell surface, and consequently reduced host susceptibility to subgroup A ASLV<sup>54</sup>. Given that the tva<sup>r</sup>, tva<sup>a</sup>, tva<sup>r</sup> and tva<sup>a</sup> alleles all contain a deletion of the same branch point signal, the same effects are also likely exerted by the tva<sup>r</sup> and tva<sup>a</sup> alleles in homoyzogotes, as well as the tva<sup>r3</sup>, tva<sup>r6</sup>, tva<sup>a3</sup>, tva<sup>a6</sup> and tva<sup>r3/a6</sup> resistant heterozygotes, as evidenced by their significantly decreased susceptibility to infection by ASLV-A. In contrast to resistant heterozygotes, the tva<sup>r3</sup>, tva<sup>r6</sup>, tva<sup>a3</sup> and tva<sup>a6</sup> susceptible heterozygotes may retain a receptor conformation that is at least partially suitable for binding of ASLV-A envelope glycoproteins and subsequent viral infection. A previously similar study were reported by Kučerová<sup>43</sup>, the deletion of W38 completely abrogates receptor activity and explains the resistance of chukar to the J subgroup of ALV; however, alleles with W38 replaced by G or E conferred susceptibility to the virus when over-expressed in the virus entry assay. Alternative splicing is not only important for normal cellular functions but also frequently is involved in disease pathogenesis<sup>37,38,41</sup>. Interestingly, published studies have identified intronic deletions causing exon skipping or intron retention in the human LDLR gene of patients with familial hypercholesterolemia<sup>4</sup>–<sup>6</sup>. Because the human LDLR gene is homologous to the tva receptor gene, such deletions as described above may be speculated as a common mechanism of mutagenesis within this gene family.

From the point of view of virus-host coevolution, it is tempting to speculate that the tva<sup>r</sup> and tva<sup>a</sup> alleles with decreased susceptibility to ASLV-A in Chinese chickens have been selected by pressure from subgroup A ASLV. Although eradication management strategies at the breeder level and high biosecurity level of flock production are not a practical means of completely eliminating the occurrence and ASLV infection. ASLV infection is known to cause a variety of neoplastic disease conditions and other production problems in affected flocks<sup>55</sup>. Under these conditions, a wide prevalence of resistance alleles in the ASLV receptor genes can be expected. To date, resistance alleles in the tva, tvb and tvc genes have been found in particular inbred lines of White Leghorns<sup>12</sup>–<sup>15</sup>. The resistance conferred by some alleles are caused by premature termination codons or frame shift mutations, such as tva<sup>r3</sup>, tvb<sup>r2</sup> and tvc<sup>r11</sup>, which do not encode any product that can carry out normal cellular functions, but their potential detrimental impact on resistant birds is unknown. Given the presence of such counter-selection and rapid evolution of ASLV envelope glycoproteins, complete resistance to ASLV entry can appear but cannot prevail and be fixed in the chicken population. Hence, we suggest that genetic variations with modest effects on both ASLV entry and natural receptor functions provided a positive selective advantage in the chicken population. Selection of mutant Tva proteins that have lost the ability to function as an ASLV-A receptor while possibly retaining the normal Tva function may have provided the greatest selective advantage, resulting in fixation of the tva<sup>r</sup> and tva<sup>a</sup> loci in the germ lines of certain lines of chickens.

The tva<sup>r</sup>, tva<sup>a</sup>, tva<sup>r3</sup> and tva<sup>a6</sup> resistant alleles are prevalent in Chinese commercial broiler lines (Table I), indicating that the potential for genetic improvement of resistance to ASLV-A is great and selective breeding for chickens genetically resistant to ASLV-A is feasible. Despite the potential benefits to be derived from breeding for enhanced resistance to ASLV-A, evaluating whether trade-offs between disease resistance and other economically important traits of chickens exist would be prudent. In fact, in a separate study we have evaluated the effects of genetic resistance to subgroup A ASLV on growth, feed efficiency and carcass traits using an F2 resource population by reciprocally crossing Huiyang Bearded chickens and fast-growing Chinese yellow broilers. The results demonstrated that genetic selection for tva<sup>r</sup>, tva<sup>a</sup>, tva<sup>r3</sup> and tva<sup>a6</sup> resistant loci can improve genetic resistance to subgroup A ASLV, but does not compromise production performance (data not shown). Selection for genetic resistance to subgroup B ASLV has been found to have no negative effect on laying performance in White Leghorn hens<sup>55</sup>. Furthermore, genetic selection for tva<sup>r</sup> and tvb<sup>a</sup> alleles can improve laying performance and growth rate, as well as greatly reduce lymphoid leukosis in White Leghorn hens<sup>43</sup>–<sup>55</sup>.

In conclusion, our study identified two novel genetic resistant alleles, tva<sup>r3</sup> and tva<sup>a6</sup>, in Chinese commercial broilers. These two resistant alleles both harbor an internal intronic deletions comprising the deduced branch point signal within the first intron and leading to alternative splicing of the tva receptor gene, resulting in significantly decreased the susceptibility to subgroups A ASLV. We also demonstrated a difference in the susceptibility to subgroup A ASLV between tva<sup>r3/a6</sup>, tva<sup>r6/a6</sup>, tva<sup>a3/a6</sup> and tva<sup>r3/a3</sup> heterozygotes and tva<sup>r3</sup>, tva<sup>a6</sup> and tva<sup>r6/a6</sup> heterozygotes. This study provides valuable insight into mechanisms of genetic resistance to ASLV and retrovirus-host coevolution.

**Methods**

**Ethics statement.** The animal experiments were conducted in accordance with the guidelines of the Guangdong province on the review of welfare and ethics of laboratory animals approved by the Guangdong province administration office of laboratory animals (GPAOLA). All the animal procedures were approved by the Animal Care Committee of the College of Animal Science, South China Agricultural University, Guangzhou, China (approval ID: 201004152).

**Amplification and analysis of tva alleles from commercial broiler lines.** Genomic DNA was prepared from blood samples of 22 commercial broiler lines using phenol-chloroform extraction. These commercial broiler lines were maintained at Guangdong Wen’s Food Group Co., Ltd. The sequence of the genomic region including exon 1, intron 1 and exon 2 of the tva gene was amplified using forward TVA1 primer 5’-GTTCACGACATTCATCCTCCTCCG-3’ and reverse TVA2 primer 5’-GGCCATTGTGGCGATCTAAGGGG-3’. The PCR procedure was as follows: an initial denaturation at 95°C for 5 min, followed by 35 cycles of 94°C for 30 s, 67°C for 45 s and 72°C for 90 s, and a final extension of 72°C for 10 min with KOD-Plus Neo (Toyobo, Tokyo, Japan). In total, 712 birds from different commercial broiler lines were genotyped. The PCR product with an expected length of 1308 bp was directly sequenced using an ABI 3730 sequencer (Applied Biosystems, Foster City, CA, USA).

**Splicing analysis by RT-PCR.** Total RNA from live samples of commercial broiler lines 208, 419, 502 and 603 were isolated using TRIZOL reagent (Invitrogen, Carlsbad, CA, USA) according to the manufacturer’s instructions. cDNA was obtained by reverse transcription of 1 µg of total RNA with ReverTra Ace<sup>®</sup> qPCR RT Master Mix with gDNA Remover (Toyobo, Tokyo, Japan). In total, 712 birds from different commercial broiler lines were genotyped. The PCR reaction product was sequenced by direct amplification from each commercial line was amplified using the following primers for the tva coding sequence was amplified using the forward TVA3 primer 5’-CGGCCATGCGGTGTGTTG-3’ containing the tva initiation codon and the reverse TVA4 primer 5’-AGCCAGGTTCACGGTACCCG-3’, which is complementary to the 3’ untranslated region. The PCR conditions were as follows: an initial denaturation at 95°C for 1 min, followed by 30 cycles of 94°C for 30 s, 58°C for 30 s and 72°C for 30 s, and a final extension of 72°C for 5 min with KOD FX (Toyobo, Tokyo, Japan). To identify the transcripts of the tva alleles and their heterozygotes, the RT-PCR products were visualized by electrophoresis on 2% agarose gels. The purified RT-PCR products were ligated into the pMD19-T vector (TaKaRa, Dalian, China) and sequenced using an ABI 3730 sequencer (Applied Biosystems).

**Construction of ASLV subgroup A reporter vector and virus propagation.** The EGP gene was isolated from the pVAX1-EGFP vector (stored at our laboratory) as an EcoRI-Xhol fragment and cloned into the ClaI2Nco adapter plasmid at the same restriction sites<sup>11,12</sup>. The resulting clones with the proper orientation of EGP were isolated as a Clal fragments and subcloned into the corresponding site of pRCASBP(A) vector<sup>11</sup>, which was kindly obtained from Stephen H. Hughes (HIV Drug Resistance Program, National Cancer Institute, USA). The resulting expression construct was designated RCASBP(A)-EGFP. The RCASBP(A)-EGFP virus, transducing the EGP reporter gene, was propagated by transfection of plasmid DNA containing the reporter vector into DF-1 cells, which are free of closely related endogenous retrovirus loci. Transfection was performed by using the X-tremeGENE 9 transfection reagent (Roche, Basel, Switzerland) according to the manufacturer’s instructions. Infection and virus spread were observed as an increasing proportion of GFP-positive cells, and virus stocks were harvested on day 7.
9 post-transfection. The cell supernatants were cleared of debris by centrifugation at 2,000 × g for 10 min at 10°C, and aliquoted viral stocks were stored at −80°C. The virus titer was determined by terminal dilution and subsequent infection of DF-1 cells, reached 10^6 IU/mL.

Preparation of CEFs and cell culture. Primary CEFs were prepared from 9 to 11-day-old embryos from commercial broilers lines 208, 419, 502 and 603 and were randomly divided into four groups with 25 birds each. These chicks were inoculated once again at five days of age. A whole blood sample from each one-day-old chick was drawn from the wing vein and then analyzed.

Animal experiment. The animal experiment design included two independent experiments with 100 birds each. Chicks randomly collected from commercial broilers lines 208, 419, 502 and 603 were propagated in growth medium containing 10% fetal bovine serum (Gibco/Invitrogen, Carlsbad, CA, USA) with 10% fetal bovine serum (Gibco/Invitrogen, Carlsbad, CA, USA), and penicillin/streptomycin (100 mg/ml each) at 37°C and 5% CO2.

RCASBP(A)-EGFP virus spread assayed by fluorescence-activated cell sorting (FACS). The infection was determined by terminal dilution and subsequent infection of DF-1 cells, reached 10^6 IU/mL.

Preparation of CEFs and cell culture. Primary CEFs were prepared from 9 to 11-day-old embryos from commercial broilers lines 208, 419, 502 and 603 and were randomly divided into four groups with 25 birds each. These chicks were maintained in four negatively pressurized biosecurity isolators under quarantine conditions and provided with water and commercial feed ad libitum. One-day-old chicks were inoculated with 2.5 S/P of avian leukosis virus subgroup A (ALV-A) strain GD08M which was kindly provided by Weisheng Cao at South China Agricultural University, P. R. China, in 0.2 ml into the abdominal cavity. These chicks were inoculated once again at five days of age. A whole blood sample from each one-day-old chick was drawn from the wing vein and used for genomic DNA isolation by the phenol–chloroform method for genotyping as described above. To determine whether blood samples of chicks were positive for ASLV-A at one month post-infection, a whole blood sample from each bird was used for preparing total RNA using the TRIZOL reagent (Invitrogen, Carlsbad, CA, USA). The coding sequence of the env gene of ALV-A was amplified using the forward H5 primer 5′-GGATGAGGTGCAATAGAAGG-3′ and reverse H6 primer 5′-AGAGAAGGATGGTTCTAAGAGA-3′. The PCR conditions were as follows: a reverse translation at 50°C for 30 min, then an initial denaturation at 94°C for 3 min, followed by 30 cycles of 94°C for 30 s, 56°C for 30 s and 72°C for 60 s, and a final extension of 72°C for 5 min with PrimeScript® One Step RT-PCR Kit Ver. 2 (TaKaRa, Dalian, China). To identify the infection status of ALV-A, the PCR products were visualized by electrophoresis on 2% agarose gels.
Acknowledgments

We thank Guangdong Wen’s Food Group Co., Ltd., Guangdong, China, for providing the commercial broiler lines 202, 203, 204, 205, 207, 208, 209, 301, 306, 406, 407, 408, 411, 413, 417, 418, 419, 501, 502, 505, 511, 603 samples, and Stephen H. Hughes from NIH Drug Resistance Program, National Cancer Institute, USA, for providing the Cla12Nco adapter plasmid and RCASBP(A) vector, as well as Weisheng Cao at South China Agricultural University, P.R. China, for providing the avian leukemia virus subgroup A strain GD08. This study was supported by the Natural Science Foundation of Guangdong Province (Grant No. S20130301313), National Modern Agricultural Industry Technology System Project of China (CARS-41) and Guangdong Province Science and technology plan project (Grant No. 2012B020306002 and Grant No. 2012B091100078).

Author contributions

W.G.C., Y.L. and Q.M.X. conceived and designed the project. W.G.C., Y.L. and H.X.L. performed the experiments. W.G.C., H.X.L. and S.C. analyzed the data. W.G.C. and H.M.Z. wrote the paper. D.M.S., H.M.Z. and F.C. contributed the materials. H.M.Z. and Q.M.X. carried out the principal investigator. W.G.C. and Y.L. contributed equally to the work.
