Many applications of quantum simulation require one to prepare and then characterize quantum states by efficiently estimating $k$-body reduced density matrices ($k$-RDMs), from which observables of interest may be obtained. For instance, the fermionic 2-RDM contains the energy, charge density, and energy gradients of an electronic system, while the qubit 2-RDM contains the spatial correlation functions of magnetic systems. Naive estimation of such RDMs requires repeated state preparations for each matrix element, which makes for prohibitively large computation times. However, commuting matrix elements may be measured simultaneously, allowing for a significant cost reduction. In this work, we design schemes for such a parallelization with near-optimal complexity in the system size $N$. We first describe a scheme to sample all elements of a qubit $k$-RDM using only $O(3^k \log^{k-1} N)$ unique measurement circuits, an exponential improvement over prior art. We then describe a scheme for sampling all elements of the fermionic 2-RDM using only $O(N^2)$ unique measurement circuits, each of which requires only a local $O(N)$-depth measurement circuit. We prove a lower bound of $\Omega(\epsilon^{-2}N^k)$ on the number of state preparations, Clifford circuits, and measurement in the computational basis required to estimate all elements of a fermionic $k$-RDM, making our scheme for sampling the fermionic 2-RDM asymptotically optimal. We finally construct circuits to sample the expectation value of a linear combination of anticommuting two-body fermionic operators with only $O(\omega)$ gates on a linear array. These circuits allow for sampling any linear combination of fermionic 2-RDM elements in $O(N^2/\omega)$ time, with a significantly lower measurement circuit complexity than prior art. Our results improve the viability of near-term quantum simulation of molecules and strongly correlated material systems.

I. INTRODUCTION

The advent of variational methods, most notably the variational quantum eigensolver [1,2], inspires hope that useful contributions to our understanding of strongly correlated physical and chemical systems might be achievable in pre-error-corrected quantum devices [3]. Following this initial work, much progress has gone into lowering the coherence requirements of variational methods [4], calculating system properties beyond ground state energies [5–7], and experimental implementation [8–11]. However, extracting data from an exponentially complex quantum state is a critical bottleneck for such applications. Initial estimates for the number of measurements required to accurately approximate the energy of a variationally generated quantum state were astronomically large, with bounds for quantum chemistry applications as high as $10^{13}$ for a system of 112 spin orbitals in minimal basis [12]. Although improving these results is critical for the scalability of variational approaches, until recently, little effort has been devoted to lowering the number of measurements needed.

A common way to estimate the energy of a quantum state during a variational quantum algorithm is to perform partial tomography [2] on a set of observables which comprise a $k$-body reduced density matrix ($k$-RDM) [13] [14]. For instance, the fermionic 2-RDM allows one to calculate such properties as energy [14], energy gradients [7,15], and multipole moments [16] of electronic systems in quantum chemistry and condensed matter problems, and further enables techniques for relaxing orbitals to reduce basis error [5,17]. By contrast, the qubit 2-RDM plays a vital role in spin systems, as it contains static spin correlation functions that can be used to predict phases and phase transitions [18], and separately contains information to characterize the entanglement generated on a quantum device [19]. Reduced density matrices thus offer a useful and tractable description of an otherwise complex quantum state.
Partial tomography to estimate a reduced density matrix may be performed by separating the observables to be tomographed into sets of mutually commuting operators. By virtue of their commutation, a unique measurement scheme may be found to measure all operators in a single set simultaneously. Subsequent measurement of noncommuting operators requires repreparation of the quantum state, so the time required to estimate a target RDM is proportional to the number of unique measurement circuits. Minimizing this number is crucial for the scalability of variational algorithms, as a naive approach requires $O(N^4)$ unique measurement circuits, which is impractical. Recent work has focused on mapping this problem to that of clique finding or coloring of a graph [20], and applying approximate algorithms to these known NP-hard problems [21]. These schemes achieve constant or empirically determined linear scaling improvements over an approach that measures each term individually [20,22–25]. However, the commutation relations between local qubit or local fermionic operators has significant regularity not utilized in naive graph-theoretic algorithms. Leveraging this regularity is critical to optimizing and proving bounds on the difficulty of tomography of quantum states.

In this work, we provide schemes for the estimation of fermionic and qubit k-RDMs that minimize the number of unique measurement circuits required, significantly decreasing the time required for partial state tomography over prior art. We demonstrate a scheme to estimate qubit k-RDMs in an $N$-qubit system in time $O(3^k \log^{k-1} N)$ [26], achieving an exponential increase over prior art. We then prove a lower bound of $\Omega(N^k)$ on the number of state preparations required to estimate fermionic k-RDMs (such as those of interest in the electronic structure problem) using Clifford circuits (including the addition of ancilla qubits prepared in the $|0\rangle$ state) and measurement in the computational basis. We describe protocols to achieve this bound for $k \leq 2$. We detail measurement circuits for these protocols with circuit depths of $O(N)$ and gate counts of $O(N^2)$ (requiring only linear connectivity) that additionally allow for error mitigation by symmetry verification [27,28]. Finally, we detail an alternative scheme to measure arbitrary linear combinations of fermionic k-RDM elements based on finding large sets of anticommuting operators. This scheme requires $O(N^4/\omega)$ measurements but has a measurement circuit gate count of only $O(\omega)$ on a linear array for a free parameter $\omega < N$.

In Table I, we provide a history of previous work in optimizing measurement schemes for the electronic structure problem and include the new results found in this work. We further include the lower bounds for the number of partitions required for the anticommuting and commuting clique cover approaches that are presented in this work.
II. BACKGROUND

Physical systems are characterized by local observables. However, the notion of locality depends on the exchange statistics of the system in question. In an $N$-qubit system, data about all $k$-local operators within a state $\rho$ are given by the (qubit) $k$-reduced density matrices, or $k$-RDMs [14]

$$k^\rho_{i_1,\ldots,i_k} = \text{Tr}_{j \neq i_1,\ldots,i_k}[\rho].$$

(1)

Here, the trace is over all other qubits in the system. To estimate $k^\rho$, we need to estimate expectation values of all tensor products of $k$ single-qubit Pauli operators $P_i \in \{X,Y,Z\}$; we call such tensor products “$k$-qubit” operators. In an $N$-fermion system, data about all $k$-body operators are contained in the (fermionic) $k$-body reduced density matrices, which are obtained from $\rho$ by integrating out all but the first $k$ particles [14]

$$k^D = \text{Tr}_{k+1,\ldots,N}[\rho].$$

(2)

Estimating $k^D$ requires estimating the expectation values of all products of $k$ fermionic creation operators $c_j^\dagger$ with $k$ fermionic annihilation operators $c_j$. For instance, the 2-RDM catalogs all four-index expectation values of the form $\langle c_{j_1}^\dagger c_{j_2}^\dagger c_j c_{j_3} \rangle$. One can equivalently describe fermionic systems in the Majorana basis,

$$\gamma_{2j} = c_j + c_j^\dagger, \quad \gamma_{2j+1} = i(c_j^\dagger - c_j),$$

(3)

in which case the fermionic $k$-RDM may be computed from the expectation values of $2k$-Majorana terms $\gamma_j$ (e.g., the 2-RDM is computed from expectation of Majorana operators of the form $\langle \gamma_j \gamma_{j+1} \gamma_{j+2} \rangle$). We call such products $2k$-Majorana operators for short.

The expectation values of the above operators may be estimated with standard error $\epsilon$ by $O(\epsilon^{-1})$ repeated preparation of $\rho$ and direct measurement of the operator. This estimation may be performed in parallel for any number of $k$-qubit operators $\hat{P}_i$ or $2k$-Majorana operators $\hat{G}_{ij}$, as long as all operators to be measured in parallel commute. This suggests that the speed of a “partial state tomography” protocol that estimates expectation values of all $k$-qubit or $2k$-Majorana operators by splitting them into a set of “commuting cliques” (sets where all elements commute) is proportional to the number of cliques required. In this work, we focus on optimizing partial state tomography schemes by minimizing this number. Necessarily, our approach is different for qubit systems (where two spatially separated operators always commute) compared to fermionic systems (where this is often not the case).

III. NEAR-OPTIMAL MEASUREMENT SCHEMES FOR LOCAL QUBIT AND FERMION OPERATORS

Partial state tomography of qubit $k$-RDMs can be efficiently performed by rotating individual qubits into the $X$, $Y$, or $Z$ basis and reading them out. These rotations define a “Pauli word” $W \in \{X,Y,Z\}^N$, where $W_i$ is the choice of basis for the $i$th qubit. Repeated sampling of $W$ allows for the estimation of expectation values of any Pauli operator $P$ that is a tensor product of some of the $W_i$—we say these operators are contained within the word. (The set of all such $P$’s is the clique corresponding to $W$ with the property that each $P$ is qubitwise commuting with the rest of operators in the word $W$.) To estimate the $k$-qubit RDM in this manner, we need to construct a set of words that contain all $k$-local operators. For $k = 2$, it is sufficient to find a set of words $W \in \{A_0,A_1\}^N$ such that each pair of qubits differ in their choice of letter in at least one word. Then, permuting over $A_0 = X$, $Y$, $Z$, and separately $A_1 = X$, $Y$, $Z$ extends the set to contain all two-qubit operators. Such a set can be found via a binary partitioning scheme for a total of $6[\log N] + 3$ cliques (see the Appendix A for details). This scheme may be further extended to arbitrary $k > 2$ with a complexity $O(3^k \log^k(N))$. The (classical) computational complexity to generate each word is at most $O(\log(N))$, and $O(N)$ to assign each qubit, making the classical computational cost to generate the set of measurements $O(6^N \log^k N)$, which is acceptably small for even tens of thousands of qubits. We add code to generate the full measurement protocol to the OpenFermion software package [33].

Fermionic $k$-RDMs require significantly more measurements to tomograph than their qubit counterparts, as many more operators anticommute. In an $N$-fermion system, the total number of $2k$-Majorana operators is $\binom{2N}{2k}$, while the size of a commuting clique of $2k$-Majorana operators may be upper-bounded by $\binom{N}{k}$ in the $N \gg k$ limit (see Appendix B). As fermionic $k$-RDMs contain expectation values of $2k$-Majorana operators, the number of cliques required to estimate all elements in the fermionic $k$-RDM scales as

$$\binom{2N}{2k}/\binom{N}{k} \sim N^{k^2}. \quad (4)$$

In terms of the resources requirement to estimate a fermionic $k$-RDM, this bound directly implies

**Theorem 1.** The number of preparations of an arbitrary $N$-fermion quantum state $\rho$ required to estimate all terms in the fermionic $k$-RDM to within an error $\epsilon$ via Clifford operations (including addition of ancilla qubits prepared in the $|0\rangle$ state) and measurement in the computational basis is bounded below in the worst case as $\Omega(\epsilon^{-N^{k^2}})$.

Proof details may be found in Appendix H. In particular, estimating the fermionic 1-RDM requires repeated preparation of $\rho$ and measurement over at least $2N - 1$ unique commuting cliques, and estimating the fermionic 2-RDM requires repeat preparation and measurement over a number of cliques at least
\[
\frac{4}{3} N^2 - \frac{8}{3} N + 1.
\]  

(5)

Maximally sized cliques of commuting 2k-Majorana operators may be achieved via a pairing scheme. If we pair the 2N individual 1-Majorana operators into N pairs \( \{ \gamma_i \gamma_j \} \), the corresponding set of operators \( i \gamma_i \gamma_j \) forms a commuting set. Any product of k of these pairs will also commute, so the set of all combinations of k pairs is a commuting clique of exactly \( \binom{N}{k} \) 2k Majoranas. We say that the 2k-Majorana operators are contained within the pairing. Curiously, each pairing saturates the bounds found in Appendix C for the number of mutually commuting 2k-Majorana operators in an N-fermion system, and thus, this scheme is optimal in the number of 2k-Majorana operators targeted per measurement circuit. However, as one 2k-Majorana operator may be contained in multiple pairings, it remains to find a scheme to contain all 2k-Majorana operators in the minimum number of pairings. For the 1-RDM, it is possible to reach the lower bound of 2N - 1 cliques by a binary partition scheme, which we detail in Appendix C. In the 2-RDM case, we are able to achieve \( \frac{10}{3} N^2 \) cliques (also detailed in Appendix C) by a divide-and-conquer approach. It remains an open question whether the factor 5/2 between our scheme and the lower bound [Eq. (5)] can be improved, either by better bounding or a different scheme.

Simultaneous estimation of the expectation value of each observable may be achieved by repeatedly preparing and measuring states in the \( i \gamma_i \gamma_j \) basis for all paired \( \gamma_i \gamma_j \) in the clique. Measuring the system in this basis is nontrivial and depends on the encoding of the fermionic Hamiltonian onto the quantum device. However, this measurement requires simply permuting the Majorana labels, which for most common encodings may be achieved by a single-particle basis rotation using Clifford gates (see Appendix F). This implies that the circuit depth should be no worse that \( O(N) \), and will not require \( T \) gates in a fault-tolerant setting. Furthermore, in many cases the measurement circuit should be able to be compiled into the state-preparation circuit, reducing its cost further.

Symmetry constraints on a system (i.e., unitary or antiunitary operators \( S \) that commute with the Hamiltonian \( H \)) force certain RDM terms to be 0 for any eigenstate of the system. For example, when a real Hamiltonian is written in terms of Majorana operators [using Eq. (3)], it must contain an even number of odd-index 1-Majorana operators, and expectation values of terms not satisfying this constraint on eigenstates will be set to 0. More generally, if a symmetry is a Pauli word \( W_{\text{symmetry}} \) such that \( W_{\text{symmetry}}^2 = 1 \), then it will divide the set of all Majorana terms into those which commute with \( W_{\text{symmetry}} \) and those which anticommute; products of odd numbers of anticommuting terms will have zero expectation value on eigenstates of the system. Given \( n \) such independent symmetries, each of which commute with half of all 1-Majorana operators (which is typical), we are able to contain all elements of the fermionic 2-RDM in a number of cliques scaling to first order as

\[
N^2 \left( \frac{10}{3} 4^{-N_{\text{sym}}} + 2^{1-N_{\text{sym}}} \right). 
\]  

(6)

(See Appendix D for details.) In Fig. 1, we show the result of an implementation of our scheme for different numbers of symmetries at small \( N \) and see quick convergence to this leading-order approximation for up to four symmetries (typical numbers for quantum chemistry problems). Code to generate this measurement scheme is added to the OpenFermion package [33].

IV. MEASURING ANTICOMMUTING LINEAR COMBINATIONS OF LOCAL FERMIONIC OPERATORS

Products of Majorana and Pauli operators have the special property that any two either strictly commute or strictly anticommute. This raises the question of whether there is any use in finding cliques of mutually anticommuting Pauli operators. Such cliques may be found in abundance when working with Majoranas; e.g., for fixed \( 0 \leq j, k, l \leq 2N \), the set \( A_{j,k,l} = \{ \gamma_i \gamma_j \gamma_k \gamma_l \} \) is a clique of 2N - 3 mutually anticommuting operators. Curiously, it turns out that asymptotically larger anticommuting cliques are not possible; the largest set of mutually anticommuting Pauli or Majorana operators contains at most 2N + 1 terms (see Appendix G for a proof). The number of anticommuting cliques required to contain all 4-Majorana operators is thus bounded below by \( \Omega(N^3) \), matching the numerical observations of Ref. [25].

Although sampling each term in an anticommuting clique \( A \) of size \( L \) requires \( O(L) \) state preparations, it is possible to measure a (real) linear combination \( \mathcal{O} = \sum_{i=1}^{L} c_i P_i \) of

![Figure 1](image-url)
clique elements in a single shot. Since all elements of $A_{j,k,l}$ share three of the same four indices, here we can associate each $P_i$ in the sum over the elements of $A_{j,k,l}$ with the Majorana $P_i = \gamma_j \gamma_k |l\rangle$. Given that $\tilde{O} = \left( \sum_{l=1}^4 \mathbb{O}_l^2 \right)^{-1/2} O$ looks like a Pauli operator ($\tilde{O}^2 = \mathbb{O}$, $\text{Tr} \{ \tilde{O} \} = 0$), and smells like a Pauli operator ($\tilde{O}^2 = 1$), it can be unitarily transformed to a Pauli operator of our choosing. In Appendix F, we show that for systems encoded via the Jordan-Wigner transformation, this unitary transformation may be achieved with a circuit depth of only $N - 2 + O(1)$ two-qubit gates. It is possible to reduce the depth further by removing Majoranas from the set. If we restrict ourselves to subsets of $\omega$ elements of $A_{j,k,l}$, the measurement circuit will have $\omega$ gates and be depth $\omega$, but $O(N^k / \omega)$ such sets will be needed to estimate arbitrary linear combinations of 4-Majorana operators. This flexibility makes this scheme very attractive in the near term, where complicated measurement circuits may be prohibited by low coherence times in near-term devices.

V. CONCLUSION

Experimental quantum devices are already reaching the stage where the time required for partial state tomography is prohibitive without optimized scheduling of measurements. This makes work developing new and more-optimal schemes for partial tomography of quantum states exceedingly timely. In this work, we show that a binary partition strategy allows one to sample all $k$-local qubit operators in an $N$-qubit system in poly-log($N$) time, reaching an exponential improvement over previous work. By contrast, in fermionic systems we find a lower bound on the number of unique measurement circuits required to directly sample all $k$-local operators of $\Omega(N^{k/2})$, an exponential separation. We develop schemes to achieve this lower bound for $k = 2$ and $k = 4$, allowing estimation of the entire fermionic 2-RDM to constant error in $O(N^2)$ time. Additionally, we demonstrate that one can leverage the anticommuting structure of fermionic systems by constructing such sets of size $1 \leq \omega \leq N$ to measure all 4-Majorana operators in $O(N^k / \omega)$ time with a gate count and circuit depth of only $\omega$, allowing one to trade off a decrease in coherence time requirements for an increase in the number of measurements required. We note that during the final stages of preparing this manuscript, a preprint was posted to arXiv which independently develops a similar scheme for measuring $k$-qubit RDMs [19]. This scheme seems to be identical to ours for $k = 2$ but uses insights about hash functions to generalize the scheme to higher $k$ with scaling of $e^{O(k) \log N}$, which improves over our bound of $O(3^k \log^{k-1} N)$ by polylogarithmic factors in $N$.

APPENDIX A: SCHEMES FOR PARTIAL STATE TOMOGRAPHY OF QUBIT $k$-RDMs

In this section, we develop methods to minimize the measurement cost for partial state tomography of qubit $k$-RDMs by minimizing the number of commuting cliques needed to contain all $k$-qubit operators. To do so, we associate a Pauli word $W \in \{X, Y, Z\}^N$ with each clique: By measuring the $i$th qubit in the $W_i$ basis, we measure every tensor product of the individual Pauli operators $W_i$. Thus, the clique associated with $W$ contains all $k$-qubit operators that are tensor products of the $W_i$—we say these operators are “contained” within the word. We then wish to find the smallest possible set of words such that every $k$-qubit operator is contained within at least one word.

We construct such a set through a $k$-ary partitioning scheme, which we first demonstrate for $k = 2$. As motivation, consider that the set of nine words (with $A, B = X, Y, Z$),

$$W_i^{(A,B)} = \begin{cases} A & \text{if } i < N/2, \\ B & \text{if } i \geq N/2 \end{cases}$$

contains all two-qubit operators that act on qubits $j < N/2$ and $k \geq N/2$. We may generalize this scheme to obtain all other two-qubit operators by finding a set of binary partitions $S_{n,0} \cup S_{n,1} = \{1, \ldots, N\}$ such that for any pair $0 \leq i \neq j \leq N$ there exists $n, a$ such that $i \in S_{n,a}$, $j \in S_{n,1-a}$. Let us define $L = \lfloor \log N \rfloor$, and write each qubit index $i$ in a binary representation, $i = [i]_L-1[i]_{L-2}, \ldots, [i]_1[i]_0$. Then, for $n = 0, \ldots, L-1$ we define

$$i \in S_{n,a} \text{ if } [i]_n = a.$$  

All $0 \leq i \neq j \leq N$ differ by at least one of their first $L$ binary digits [as shown in Fig. 2(a)], so the set of words $W_i^{(A,B)}$ constructed as

$$W_i^{(A,B)} = \begin{cases} A & \text{if } i \in S_{n,a}, \\ B & \text{if } i \in S_{n,1-a} \end{cases}$$

defines a set of cliques that contain all two-qubit operators. As $W_i^{(A,A)}$ is the same word for every $n$, we need choose only this word once, and so the number of cliques may be reduced to $6L + 3$.

To see how the above may be extended to $k > 2$, let us consider $k = 3$. We wish to find 3-ary partitions $S_{n,a} = \{1, \ldots, N\}$ that, given any set $i_1$, $i_2$, $i_3$, we can find
set \( i \) in a scheme that achieves this in Fig. 2(b). We iterate first over words that contain all three-qubit operators. We illustrate a scheme to construct a set of \( O(\log^2 N) \) cliques that contain all three-qubit operators.

In this Appendix, we detail the bounds on the size of commuting cliques of Majorana operators. Let us call the largest number of mutually commuting \( k \)-Majoranas that are a product of \( l \) unique terms (i.e., \( l \) unique 1-Majoranas) \( M_l^k \). (For an \( N \)-fermion system, we will eventually be interested in the case where \( l = 2N \).) We wish to bound this number \( M_l^k \) by induction. All 1-Majorana operators anticommute, so \( M_l^1 = 1 \). Then, let us consider the situation where \( k \) is even and when \( k \) is odd separately. Suppose we have a clique of \( M_l^k \) \( k \)-Majorana operators with \( k \) even. As there are only \( l \) unique terms, and these \( k \)-Majoranas contain \( kM_l^k \) individual terms each, there must be a clique of \( [kM_l^k]/I \) of these operators that share a single term \( \gamma_0 \). We might write each such operator in the form \( \pm \gamma_0 \Gamma_i \), where \( \Gamma_i \). As \( [\gamma_0 \Gamma_i, \gamma_0 \Gamma_j] = 0 \) if and only if \( [\Gamma_i, \Gamma_j] = 0 \), this gives a clique of \( kM_l^k/I \) commuting \( (k-1) \)-Majorana operators on \( l-1 \) unique terms, so we must have

\[
\frac{kM_l^k}{I} \leq M_{l-1}^{k-1}, \quad k \text{ even.} \tag{B1}
\]

Now, consider the case where \( k \) is odd, let us again assume we have a clique of \( M_l^k \) commuting \( k \)-Majoranas. Two products of Majorana operators anticommute unless they share at least one term in common, so let us choose one \( k \)-Majorana \( \Gamma_i \) in our set; each \( k \)-Majorana must have at least one of the \( k \) terms in \( \Gamma_i \), so at least one such term is shared between \( [M_l^k]/k \)-Majoranas in our set. Removing this term gives a clique of \( [M_l^k]/k \) \((k-1)\)-Majorana operators on \( l-1 \) unique terms, and so we have

\[
\frac{M_l^k}{k} \leq M_{l-1}^{k-1}, \quad k \text{ odd.} \tag{B2}
\]

These equations may be solved inductively to lowest order in \( k \) to obtain

\[
M_l^k \sim l^{k/2}. \tag{B3}
\]

This bound can be strengthened in the \( l \gg k \) limit, as here the largest commuting cliques of odd-\( k \)-Majoranas must share a single term \( \gamma_0 \). This can be seen as when \( k \) is odd, large sets of commuting \((k-1)\)-Majoranas contain many operators that do not share any terms—a set of \( k-1 \) commuting operators that share a single term can be no
larger than approximately \(l^{(k-3)/2}\). Formally, let us consider a set \(C\) of commuting \(k\)-Majoranas, choose \(\Gamma \in C\), and write \(\Gamma = \gamma_1, \ldots, \gamma_k\). Then, we may write \(C = \bigcup_i C_i\), where \(C_i\) is the subset of operators in \(C\) that contain \(\gamma_i\) as a term. If there exists \(\Gamma' \in C/C_i\) (i.e., \(\Gamma'\) commutes with all operators in \(C_i\) but does not itself contain \(\gamma_i\)), we may divide \(C_i\) into \(k\) subsets of Majoranas that share the individual terms in \(\Gamma'\), and so \(|C_i| \leq k^{l(k-3)/2}\). If this is true for all such \(C_i\), we have then \(|C| \leq \sum_i |C_i| \leq k^3 l^{(k-3)/2}\). As this scales sub-optimally in the large-\(l\) limit, \([34]\) we must have that \(C/C_i\) is empty for some \(C_i\). Then, \(C_i = C\), and we can bound

\[
M_i^k \leq M_{i-1}^{k-1}, \quad \text{odd.} \tag{B4}
\]

This leads to the tighter bound (assuming \(l\) even)

\[
M_i^k \leq \frac{l!!}{(l-k)!!k!!}, \tag{B5}
\]

where the double factorial implies we multiply only the even integers \(\leq k\). Then, when \(l = 2N\), for even \(k = 2n\) we see

\[
M_{2N}^{2n} \leq \frac{2N!!}{(2N-2n)!!2n!!} = \frac{2N!}{2^{N-n}(N-n)!2^n n!} = \binom{N}{n} \tag{B6}
\]

This is precisely the size of the cliques obtained by pairing, proving this scheme is optimal in the large-\(N\) limit.

In practice, we observe that Eq. (B4) is true for \(k = 3\) whenever \(l \geq l_{\text{crit},3} 15\) (i.e., for greater than eight-fermion systems). This is because the largest set of commuting 3-Majoranas that do not share a single common element can be found to be (up to relabeling) \(\{\gamma_0 \gamma_1 \gamma_2, \gamma_0 \gamma_3 \gamma_4, \gamma_0 \gamma_5 \gamma_6, \gamma_1 \gamma_3 \gamma_5, \gamma_1 \gamma_4 \gamma_6, \gamma_2 \gamma_3 \gamma_5, \gamma_2 \gamma_4 \gamma_6\}\), which contains seven terms. The above argument implies that \(l_{\text{crit},k}\) scales at worst as \(k^2\); however, the bounds obtained here are rather loose, and we expect it to do far better.

**APPENDIX C: DETAILS OF MEASUREMENT SCHEMES FOR FERMIonic SYSTEMS**

We now construct asymptotically minimal sets of cliques that contain all 2-Majorana and 4-Majorana operators. 2-Majorana operators that share any term do not commute, so our commuting cliques of 2-Majorana operators must contain only nonoverlapping pairs of Majorana terms. Equivalently, we need to find a set of pairings of \(\{0, \ldots, 2N\}\) such that each pair \((i, j)\) appears in at least one pairing. This may be achieved optimally for \(N\) a power of 2 via the partitioning scheme outlined in Fig. 3(a). We first split \(\{1, \ldots, 2N\}\) into a set of \(N2^{-n}\) contiguous blocks for \(n = 0, \ldots, \log(2N)\),

\[
\sum_{n=0}^{\log N} 2^n = 2N - 1 \tag{C3}
\]

matching exactly the lower bound calculated in the main text. The above technique needs slight modification when \(N\) is not a power of 2 to make sure that when \(|B_{2m}'| \neq |B_{2m+1}'|\), unpaired elements are properly accounted for, but the above optimal scaling may be retained. Code to generate an appropriate set of pairings is added to the OpenFermion package [33].

As all operators in one of the above cliques \(C_{a,n}\) commute, their products commute, and the set

\[
\{\gamma_i \gamma_j, \gamma_i \gamma_k, \gamma_i' \gamma_j, \gamma_i' \gamma_k \in C_{a,n}\} \tag{C4}
\]
is clearly a clique of commuting 4-Majorana operators. However, each 2-Majorana operator is guaranteed to be in only one of the cliques $C_{n,m}$, so this set of cliques will not yet contain all 4-Majorana operators. To fix this problem, we aim to construct a larger set $\{C_n\}$ of cliques of commuting 2-Majorana operators, such that for every set $\gamma_1, \gamma_2, \gamma_3, \gamma_4$ there exists one $C_n$ containing both $\gamma_1, \gamma_2, \gamma_3, \gamma_4$ (for some permutation of $a, b, c, d = 1, 2, 3, 4$). This set may be constructed by the strategy illustrated in Fig. 3(b). For each $I = i_1, i_2, i_3, i_4$, choose the smallest $n$ such that $I \subset B_n$ for some $m$. This implies that the $\{B_m\}$ split $I$ into two parts: $I_a = I \cap B_{2m+a}$, for $a = 0, 1, 2, 3$. Suppose first $|I_0| = 2$, [case 1 in Fig. 3(b)]. In this case, by iterating over all pairs of elements in $B_n$, and subsequently all pairs of elements in $B_{2m+1}$, we at some point simultaneously pair the elements of $I_0$ and the elements of $I_1$, as required. This iteration may be performed in parallel for each $m$, making the total number of cliques generated at each $n [B_{2m}]^2 = 4^{n-1}$. Now, suppose $|I_0| = 3$ (case 2 in Fig. 3), or $|I_0| = 1$ as the two situations are equivalent. Let $n' < n$ be the smallest number such that $I_0 \subset B_{n'}$, for some $m'$, and we may split $I_0$ into two sets $I_{0,2} = I_0 \cap B_{2m+a}$ for $a = 0, 1, 2$. Of the three elements in $I_0$, two of them must either lie in $I_{0,0}$ or $I_{0,1}$—suppose without loss of generality that $|I_{0,0}| = 2$. Then, by iterating over all pairs within $B_{2m+1}$, and all pairs between elements of $B_{2m+1}$ and $B_{2m+1}$, we at some point pair both elements in $I_{0,0}$ and both elements in $I_{0,1}$.

This pairing needs to occur for all $n > n'$, which implies we need to iterate over all combinations of pairs between elements of $B_{2m+1}$ and $\{1, \ldots, 2N\} / B_{2m+1}$ (while iterating over pairs within $B_{2m+1}$). This iteration may be performed in parallel for each $m'$ at each $n'$. First, iterate over all possible pairings of $B_{2m+1}$ and $B_{2m+1}$ [which requires $O(2^{2n'})$ iterations]. Then, iterate over all pairs between $B_{2m+1}$ and $B_{2m+1}$ for all combinations of $a_0, a_1 = 0, 1$ (requiring $4 \times 2^{n'}$ iterations). Simultaneously, iterate over all pairs within $B_{2m+1}$ and $B_{2m+1}$ (requiring again $2^{n'}$ iterations). This generates $4 \times 4^{n'}$ cliques at each $n'$. The total number of cliques we then require to contain all 4-Majorana operators using this scheme is

$$\sum_{n'=1}^{[\log N]} N 2^{n'} + \sum_{n=1}^{[\log N] + 1} 4^{n'} \sim \frac{10}{3} N^2.$$  

(C5)

**APPENDIX D: REDUCING OPERATOR ESTIMATION OVER SYMMETRIES**

Given a set $\{S_i\} \subset \mathbb{D}^N$ of $N_{sym}$ mutually commuting Pauli operators that are symmetries ($[S_i, H] = 0$), we can simultaneously diagonalize both the Hamiltonian and the symmetries, implying that we can find a ground state $\rho$ such that $\text{Tr}[\rho P] = 0$ for each $P$ that does not commute with $S_i$. In the case of a degenerate ground state eigenspace, not all states will necessarily have this property (as symmetries may be spontaneously broken). However, any such $P$ will not appear in the Pauli decomposition of the Hamiltonian, and so estimation of this RDM term is not necessary to calculate the energy of the state. The commutation of a $k$-Majorana operator $\Gamma$ with a Pauli operator symmetry $S_j$ may be seen immediately by counting how many of the $k$ individual terms anticommutate with $S_j$; if this number is even, then $[\Gamma, S_j] = 0$. This fact implies that we can separate individual 1-Majorana operators into bins $B_j$ with $\delta \in \{0, 1\}^{N_{sym}}$ a commutation label:

$$\gamma_j \in B_j \rightarrow \begin{cases} \gamma_j S_i = \gamma_j & \text{iff } s_i = 0, \\ \gamma_j S_i = -\gamma_j & \text{iff } s_i = 1. \end{cases}$$  

(D1)

Let $\delta(\gamma_j)$ denote the label of the bin $\gamma_j$ may be found in, and we may generalize to all $k$-Majorana operators $\Gamma = \prod_{j=1}^k \gamma_j$:

$$s_i \left( \prod_{j=1}^k \gamma_j \right) = \sum_{l=1}^k s_l(\gamma_j) \mod 2.$$  

(D2)

To estimate the symmetry-conserved sector of the 2-RDM, we are then interested in constructing a set of cliques of 4-Majorana operators in $B_j$. These operators take the form $\gamma_j \gamma_j \gamma_j \gamma_j$, where $\delta(\gamma_j) = \delta$, $\delta(\gamma_j) = \delta + \delta$, $\delta(\gamma_j) = \delta + \delta$, $\delta(\gamma_j) = \delta + \delta$. (Recall here that in binary vector arithmetic, $\delta + \delta \mod 2 = 0$.) We construct cliques for the above in two steps. First, we iterate over all quadruples within each bin $B_j$ (using the methods in Appendix C). This covers all of the above operators where $\delta = 0$, and may be done simultaneously with cost $\frac{10}{3} B^2$, where $B$ is the size of the largest bin. Then, we iterate between bins $B_j$ and $B_{j+\delta}$ for all $\beta \in \{0, 1\}^{N_{sym}}$ with $\beta_0 = 0$. Such an iteration achieves all pairs above—either $\alpha_0 = 0$ and we pair bins $B_{j+\delta}$ with $B_{j+\delta}$ when we pair $B_{j+\delta}$ with $B_{j+\delta}$, or $\delta_0 = 0$ (and we pair bins $B_{j+\delta}$ with $B_{j+\delta}$), or $\delta_0 = 0$ when we pair $B_{j+\delta}$ with $B_{j+\delta}$, or $\delta_0 = 0$ (and we pair bins $B_{j+\delta}$ with $B_{j+\delta}$). We must perform this pairing in parallel, i.e., construct a set of $2^{N_{sym}}$-tuples by drawing one element from each $B_j \times B_{j+\delta}$ such that every two elements appear in at least one tuple. In Appendix E, we describe how this iteration may be achieved. The total cost of the above is then $2^{N_{sym}} [B^2 + 2 B \ln(B) + \ln(B)]^2$. It is common for most symmetries to divide the set of Majoranas in two, in which case $B = 2N \times 2^{-N_{sym}}$, and our clique cover size is

$$N^2 \left( \frac{10}{3} 4^{-N_{sym}} + 2^{1-N_{sym}} \right) + O(N \ln(N)).$$  

(D3)
Algorithm 1. Iterate over symmetry-conserved 2-RDM elements. Here, iterQuad and pairBetween are described in Appendix C, and parallelIterate in Algorithm 2.

Construct bins $B_j$.
quadIter = {}
for $\vec{s}$ in $\{0,1\}^{N_{sym}}$ do
  quadIter[$\vec{s}$] = iterQuad($B_j$)
end for
while any iterator in quadIter is not stopped do yield [next (iterator) for iterator in quadIter if iterator is not stopped]
end while
seriesIterate(quadIter)
for $\vec{b}$ in $\{0,1\}^{N_{sym}−1}$, $\beta \neq 0$ do
  Left-append 0 to beta [i.e., $\beta = (0, \ldots, \beta)$]
  quadIter = {}
  for $\vec{s}$ in $\{0,1\}^{N_{sym}}$, $h(\vec{s} + \vec{b}) \geq h(\vec{s})$ do
    quadIter[$\vec{s}$] = pairBetween($B_{\vec{s} + \vec{b}}$).
  end for
  parallelIterate(quadIter)
end for

We summarize our method in Algorithm 1 [where we use $h(\vec{s})$ as the Hamming weight of a binary vector $\vec{s}$].

**APPENDIX E: PARALLEL ITERATION OVER PAIRINGS**

If we wish to iterate over all pairs of two lists of $L$ elements each, clearly we must perform at least $L^2$ total iterations, and the optimal strategy is trivial (two loops). However, if we wish to iterate over all pairs between $K = 3$ or more lists of $L$ elements (i.e., generate a set of $K$-tuples such that each pair appears as a subset of one tuple), such an optimal strategy is not so obvious. When $K$ is less than the smallest factor of $L$, a simple algorithm works as described in Algorithm 2. We can see that this algorithm works, for suppose $j k_1 + l = a \mod L$ and $j k_2 + l = b \mod L$ for two separate values of $j$, $l$, $i$, we have, $j_1 k_1 + l_1 = j_2 k_2 + l_2 \mod L$. Then, we have $j_1 (k_1 - k_2) = j_2 (k_1 - k_2) \mod L$, and as $k_1$, $k_2$ are smaller than the lowest factor of $L$, gcd($k_1 - k_2$, $L$) = 1, implying $j_1 = j_2$. This scheme achieves the optimal $L^2$ total iterations, although the reliance on $K$ being smaller than the lowest factor of $L$ is somewhat unsavory. We hypothesize that the asymptotic $L^2$ is indeed achievable for all $K \leq L$, but we have been unsuccessful in our search for a construction. Instead, for composite $L$, we suggest padding each list to have length $L'$, being the first number above $L$ that achieves this requirement. The prime number theorem implies that $L' - L \sim \log(L)$ if $K \leq L$ (as then we require at worst to find the next prime number), This gives the scheme runtime $L^2 + 2L \log(L) + \log(L)^2$, which is a relatively small subleading correction.

Algorithm 2. parallelIterate: Iterate over $K$ lists $dataArray[0], \ldots, dataArray[K-1]$ of $L$ elements, generating all pairs between elements in separate lists. Assumes $K$ is less than the smallest factor of $L$.

for $j = 0$ to $L - 1$ do
  for $k = 0$ to $L - 1$ do
    thisTuple = $[dataArray[k][jk + l \mod L]$ for $k = 0$ to $K - 1$
    yield thisTuple
  end for
end for

**APPENDIX F: MEASUREMENT CIRCUITRY FOR FERMIONIC RDMS**

Direct measurement of products of Majorana operators is a more complicated matter than measurement of Pauli words (which require only single-qubit rotations). However, when the fermionic system is encoded on a quantum device via the Jordan-Wigner transformation [35], a relatively easy measurement scheme exists. Within this encoding, we have

$$i y_{2n} y_{2n+1} = Z_n, \quad (F1)$$

so if we can permute all Majorana operators such that each pair $(y_i, y_j)$ of Majoranas within a given clique is mapped to the form $(y_{2n}, y_{2n+1})$, they may be easily read off. To achieve such a permutation, we note that the Majorana swap gate $U_{i,j} = e^{(\pi/4) y_i y_j}$ satisfies

$$U_{i,j} y_k U_{i,j} = \begin{cases} y_k & \text{if } i,j \neq k, \\ y_j & \text{if } k = i, \\ -y_i & \text{if } k = j. \end{cases} \quad (F2)$$

And so repeated iteration of these unitary rotations may be used to “sort” the Majorana operators into the desired pattern. This may be performed in an odd-even search format [36]. At each step $t = 1, \ldots, N$, we decide for each $n = 1, \ldots, N$ whether to swap Majoranas $2n$ and $2n + 1$, and then whether to swap Majoranas $2n$ and $2n - 1$. Within the Jordan-Wigner transformation these gates are local,

$$U_{2n,2n+1} = e^{-i(\pi/4) Z_n}, \quad U_{2n-1,2n} = e^{-i(\pi/4) Y_n Y_n}, \quad (F3)$$

and so each time step is depth 3, for a total maximum circuit depth of $3N$ and total maximum gate depth $3N^2$. (To see that only $N$ time steps are necessary, note that each Majorana can travel up to two positions per time step.) Following the Majorana swap circuit, all pairs of Majoranas that we desire to measure will be rotated to neighboring positions and may then be locally read out. As each Majorana swap gate commutes with the global parity $\prod_{i=1}^N y_i$, these operators will be measurable alongside the clique as the total qubit parity $\prod_{i=1}^N Z_i$, allowing for error mitigation by symmetry.
verification [27,28]. As the above circuit corresponds just to a basis change, for many variational quantum eigensolvers it may be precompiled into the preparation itself, negating the additional circuit depth entirely.

As an alternative to the above ideas, it is possible to extend the partitioning scheme for measuring all $k$-qubit operators to a scheme to sample all fermionic 2-RDM elements via the Bravyi-Kitaev transformation [37,38]. This transformation maps local fermion operators to $k = O(\log N)$ qubit operators, and so using our approach the resulting scheme would require $O(3^k \log^{k-1} N) = (3 \log N)^{O(\log N)}$ unique measurement. Although this is superpolynomial, it is a slowly growing function for small $N$ and also has the advantage that the measurement circuits themselves are just single-qubit rotations. Furthermore, as the set of fermion operators is very sparse in the sense that it themselves are just single-qubit rotations. Furthermore, as $N$ may be precompiled into the preparation itself, negating the additional circuit depth entirely.

Intriguingly, for $P_i, P_j \in A_{ij,k,l}$, we have that $P_i P_j = \gamma_l \gamma_{l+1}$, which maps to a two-qubit operator under the Jordan-Wigner transformation (as noted previously). This implies a measurement circuit for these sets may be achieved with only linear gate count and depth, linear connectivity, and no additional ancillas. We can slightly reduce the depth by simultaneously removing the $P_i$ from the “top” and “bottom”; i.e., we remove $P_{2N-3}$ by rotating with $P_{2N-4}$ at the same time as removing $P_1$ by rotating with $P_2$, until after exactly $N - 2$ layers, we have only the term $P_N$ remaining. All generators in this unitary transformation commute with the parity $\prod_{i=1}^{2N} \gamma_i$, implying that it remains invariant under the transformation and may be read out alongside $P_N$. [This circuit may require an additional $O(1)$ gates if $P_N$ is not mapped to products of $Z$, via the Jordan-Wigner transformation.]

### APPENDIX G: PROOF THAT THE MAXIMUM SIZE OF AN ANTICOMMUTING CLIQUE OF PAULI OR MAJORANA OPERATORS IS $2N+1$

We prove this set result in general for the Pauli group $\mathbb{P}^N$, and note that as the Jordan-Wigner transformation maps Majorana operators to single elements of $\mathbb{P}^N$, the same is true for this. We first note that elements within an anticommuting clique $S \subset \mathbb{P}^N$ may not generate each other; let $\prod_{i=1}^{n} P_i = P_j \in S$, and if $n$ is odd $[P_i, P_j] = 0$ for any $P_i$ in the product, while if $n$ is even $[P_k, P_j] = 0$ for any $P_k$ not in the product. (The one exception to this rule is if one cannot find any such $P_k$, i.e., when $P_j = \prod_{i \neq j, \rho \in S} P_i$.) Then, note that each element $P \in \mathbb{P}^N$ commutes with precisely half of $\mathbb{P}^N$ and anticommutes with the other half. This can be seen because a Clifford operation $C$ exists such that $C^T PC = Z_1$, which commutes with all operators of the form $X_1 P_1$ and $Y_1 P_1$ and anticommutes with all operators of the form $X_i P_i$ and $Y_i P_i$, and these operators will be mapped to other Pauli operators when the transformation is undone.

We may extend this result: A set $S = \{P_1, \ldots, P_n\}$ of $n$ nongenerating anticommuting elements in $\mathbb{P}^N$ splits $\mathbb{P}^N$ into $2^n$ subsets $P_{\vec{b}}$ (with $\vec{b} \in \mathbb{Z}_2^n$), where $Q \in P_{\vec{b}}$ commutes with $P_i$ if $b_i = 0$ (and anticommutes if $b_i = 1$). To see that all $P_{\vec{b}}$ must be the same, note that given an operator $Q \in P_{\vec{b}}$, $P_i P_j Q \in P_{\vec{b} \oplus \vec{b}_i \oplus \vec{b}_j}$ (as $P_i P_j$ anticommutes with $P_i$ and $P_j$ but commutes with all other elements in $S$), so $|P_{\vec{b}}|$ and $|P_{\vec{b} \oplus \vec{b}_i \oplus \vec{b}_j}|$ are the same size. Similarly, if $Q \in P_{\vec{b}}$, $P_i Q \in P_{\vec{b} \oplus \vec{b}_i \oplus \vec{b}_j}$. If $n$ is even, this is sufficient to connect each element in $P_{\vec{b}}$ to an element in $P_{\vec{b}}$, forcing all to be the same size. However, if $n$ is odd the above will not connect $P_{\vec{b}}$ and $P_{\vec{b}}$ unless $|\vec{b}| = |\vec{b}^\prime|$ mod 2. We note that $\bigcup_{|\vec{b}| = \text{mod} \ 2} P_{\vec{b}}$ is the set of elements that commute with $\prod_{P_i \in S} P_i$, and thus must be precisely half of $\mathbb{P}^N$. This proves that the set of operators in $\mathbb{P}^N$ that anticommute with all elements in $S$ is of size $4^N/2^N$. This must be an integer, so $n \leq 2N$. Then, when $n = 2N$ there is precisely one element that anticommutes with all operators in $S$:
\[ \prod_{i \in S} P_i, \] and we may add this to \( S \) to get the largest possible set of operators. Such a set is unitarily equivalent to the set of \( 2N \) Majorana operators \( \gamma_i \) and the global parity \( \prod_{i=1}^{2N} \gamma_i \).

APPENDIX H: PROOF OF THEOREM 1

To bound the number of preparations of a state \( \rho \) required to estimate a fermionic \( k \)-RDM, we first establish a correspondence between the allowed measurement protocols and measurement of a set of commuting Pauli operators on the original state \( \rho \). As \( 2k \)-Majorana operators are Pauli operators, this implies that an estimate of the expectation value \( \langle \Gamma_i \rangle \) of each \( 2k \)-Majorana operator \( \Gamma_i \) converges with variance

\[
\text{Var}(\langle \Gamma_i \rangle) \leq \frac{(1 - \langle \Gamma_i \rangle)(1 + \langle \Gamma_i \rangle)}{4M_i},
\]

where \( M_i \) is the number of preparations and measurements of \( \rho \) in a basis containing \( \Gamma_i \). We then show the existence of a worst-case state for which this upper bound is tight, which implies that to estimate \( \langle \Gamma_i \rangle \) with error \( \epsilon \) we require \( M_i \sim \epsilon^{-2} \) preparations and measurements of \( \rho \) in a basis containing \( \Gamma_i \). To estimate expectation values of all \( \binom{2N}{2k} \) \( 2k \)-Majorana operators to error \( \epsilon \), we need for each operator \( M_i \) measurements in a basis containing this operator. As we establish that our measurement scheme allows only such measurements in parallel if the operators commute, the bound derived in Appendix B directly bounds the number of operators that may be estimated per preparation of \( \rho \) to \( \langle \gamma \rangle \), and the result follows by Eq. (4).

We now show that our measurement protocol allows only for estimation of commuting Pauli operators. By definition, Clifford operators map Pauli operators to Pauli operators, so any measurement of a state \( \rho \) that consists of a Clifford circuit \( U_{\text{Cl}} \) and subsequent readout in the computational basis is equivalent to a measurement of the commuting Pauli operators \( \{ U_{\text{Cl}}^i Z_j U_{\text{Cl}} \} \). (The same is true of any tensor product \( \{ U_{\text{Cl}}^i \otimes_j Z_j U_{\text{Cl}} \} = \prod_{i,j} U_{\text{Cl}}^i Z_j U_{\text{Cl}} \) on \( \rho \), where the \( \otimes_j \) is taken over any set of qubits, and the following arguments remain true if \( Z_j \) is replaced by \( \otimes_j Z_j \) and \( Z_j \) it remains to show that the number of preparations is unaffected by the addition of \( N_a \) ancilla qubits in the \( |0\rangle \) state. Under such an addition, we may still invert the measurement \( U_{\text{Cl}}^i Z_j U_{\text{Cl}} = P_{j,a} \otimes P_{j,a} \), where \( P_{j,a} \) and \( P_{j,a} \) are Pauli operators on the system and the ancilla qubits, respectively. By construction, the state is separable across the bipartition into system and ancilla qubits, so \( \langle P_{j,a} \otimes P_{j,a} \rangle = \langle P_{j,a} \rangle \langle P_{j,a} \rangle \). Then, as we require our ancilla qubits to be prepared in the \( |0\rangle \) state, \( \langle P_{j,a} \rangle = 0 \) unless \( P_{j,a} \) is a tensor product of \( I \) and \( Z \), in which case \( \langle P_{j,a} \rangle = 1 \). If \( \langle P_{j,a} \rangle = 0 \), a measurement of \( Z_j \) does not yield any information about \( \langle P_{j,a} \rangle \), while if \( \langle P_{j,a} \rangle = 1 \), a measurement of \( Z_j \) yields exactly the same information as a direct measurement of \( P_{j,a} \).

Finally, we argue for the existence of a state for which Eq. (H1) is tight. Equation (H1) will not be tight for every state: by constraining a fermionic \( k \)-RDM to the positive cone of \( N \)-representable states, Pauli operators with expectation values close to \( \pm 1 \) (and thus, small variance) constrain the expectation values of anticommuting operators near \( 0 \) below this limit. This beneficial covariance is of particular importance when taking linear combinations of RDM elements, e.g., to calculate energies \[ \text{30} \]; however, it requires a state to have highly nonregular structure, which in general will not be the case (or known \( a \) priori). The simplest example of an unstructured state is the maximally mixed state on \( N \) fermions; by definition, all measurements of this state are uncorrelated, and the variance on estimation of all terms is \( \text{Var}(\langle \Gamma_i \rangle) = (1/4M_i) \), which achieves the upper bound in Eq. (H1).
