Chromosome-level genome assembly and manually-curated proteome of model necrotroph *Parastagonospora nodorum* Sn15 reveals a genome-wide trove of candidate effector homologs, and redundancy of virulence-related functions within an accessory chromosome

Stefania Bertazzoni 1, Darcy A. B. Jones 1, Huyen T. Phan 1*, Kar-Chun Tan 1* and James K. Hane 1,2*

**Abstract**

**Background:** The fungus *Parastagonospora nodorum* causes septoria nodorum blotch (SNB) of wheat (*Triticum aestivum*) and is a model species for necrotrophic plant pathogens. The genome assembly of reference isolate Sn15 was first reported in 2007. *P. nodorum* infection is promoted by its production of proteinaceous necrotrophic effectors, three of which are characterised – ToxA, Tox1 and Tox3.

**Results:** A chromosome-scale genome assembly of *P. nodorum* Australian reference isolate Sn15, which combined long read sequencing, optical mapping and manual curation, produced 23 chromosomes with 21 chromosomes possessing both telomeres. New transcriptome data were combined with fungal-specific gene prediction techniques and manual curation to produce a high-quality predicted gene annotation dataset, which comprises 13,869 high confidence genes, and an additional 2534 lower confidence genes retained to assist pathogenicity effector discovery. Comparison to a panel of 31 internationally-sourced isolates identified multiple hotspots within the Sn15 genome for mutation or presence-absence variation, which was used to enhance subsequent effector prediction. Effector prediction resulted in 257 candidates, of which 98 higher-ranked candidates were selected for in-depth analysis and revealed a wealth of functions related to pathogenicity. Additionally, 11 out of the 98 candidates also exhibited orthology conservation patterns that suggested lateral gene transfer with other cereal-pathogenic fungal species. Analysis of the pan-genome indicated the smallest chromosome of 0.4 Mbp length to be an accessory chromosome (AC23). AC23 was notably absent from an avirulent isolate and is predominated by mutation hotspots with an increase in non-synonymous mutations relative to other chromosomes. Surprisingly, AC23 was deficient in effector candidates, but contained several predicted genes with redundant pathogenicity-related functions.
Conclusions: We present an updated series of genomic resources for *P. nodorum* Sn15 – an important reference isolate and model necrotroph – with a comprehensive survey of its predicted pathogenicity content.

**Background**

The fungus *Parastagonospora nodorum* causes septoria nodorum blotch (SNB) of wheat (*Triticum aestivum*) and is a model species for necrotrophic plant pathogens. In order to provide insight on the evolutionary history and gene repertoire of this pathogen, a genome assembly of *Parastagonospora nodorum* model isolate Sn15 was first reported in 2007 [1]. This used Sanger shotgun sequencing of a genomic BAC library which produced a 37.5 Mbp draft genome reference with 108 scaffolds and 10,762 genes. It was the first species among the class Dothideomycetes for which a whole-genome reference was available [1] and has been used as a model species for cereal necrotrophs. This draft genome resource contributed to the discovery of three proteinaceous necrotrophic effectors (NEs) corresponding to known gene loci - ToxA [2], Tox1 [3] and Tox3 [4] - which are major host-specific virulence determinants in *P. nodorum*. The presence of additional NEs have been detected via their interaction with quantitative trait loci (QTL) corresponding to host sensitivity loci, but the genes encoding these effectors have not yet been identified [5–11] and others may have not yet been uncovered. In order to discover novel effectors in *P. nodorum* and in other fungal plant pathogens, it is important to ensure that the genome assembly and gene annotations are as accurate and reliable as possible.

Recent advances in long-read genome sequencing technologies, and established genetic and physical mapping techniques, have made whole-chromosome assembly of microbial genomes readily achievable [12–18]. Three decades ago, chromosome size and number estimates via pulsed-field gel electrophoresis (PFGE) of 11 *P. nodorum* isolates had estimated a range from 14 to 19, totalling 28 to 32 Mbp, ranging from 0.4 to 3.5 Mbp in length, with the smallest observed only in wheat and barley-infecting isolates [19]. The *P. nodorum* Sn15 genome assembly was progressively overimproved after subsequent years. It was updated in 2013 reducing the number of scaffolds from 108 to 91 [20], and again in 2016 with revised gene annotations that were supported by protein and transcriptome alignments and manual curation [21–23]. Leveraging these resources, comprehensive analyses of its genomic landscape and genome-based processes contributing to pathogenic adaptations have extended to transposable elements (TE) and gene repeats [1, 24, 25], repeat-induced point mutations (RIP) [24–26], mesosynteny [27], and multiple comparative genomics studies [14, 15, 23, 28, 29]. Initially, the Sn15 reference isolate was compared to a hyper-virulent isolate (Sn4) and a non-aggressive isolate (Sn79–1087) lacking known effector genes ToxA, Tox3 and Tox1 [20, 23]. These newly gained information and resources have played a vital role in studying important pathogenicity gene candidates. Subsequent comparison to an international panel (across 10 countries) of 22 *P. nodorum* and 10 *Parastagonospora avenae* isolates indicated presence-absence variation (PAV) - with notable absences in the ‘avirulent’ Sn79–1087 isolate assembly - of known effector loci and of large regions (i.e. scaffolds 44, 45, 46 and 51) [23], which was supplemented by a predictive analysis of accessory chromosome (AC) or region (AR) sequence properties (scaffolds 50 and 69) [29]. These large PAV regions were indicative of ACs/ARs that are associated with host-specific virulence in numerous fungal species [30], but this could not be confirmed with an unfinished genome assembly. In 2018, long-read-based genome assemblies were generated for 3 *P. nodorum* isolates (Sn4, Sn79–1087 and Sn2000) with 22 to 24 contigs [15]. Analysis of the Sn4 genome revealed that ‘contig23’ (~0.48 Mbp) was absent in Sn79–1087 and therefore considered an AC. This study also used transcriptome data from the Sn15 reference isolate to ‘auto-annotate’ genes in Sn4, and subsequently trained gene prediction software on the Sn4 annotations, which was used to perform in silico prediction of genes in the remaining isolates [15]. A follow up study in 2019 compared these four assemblies to NGS-based assemblies for a panel of 197 isolates from the United States, highlighted widespread diversifying selection within predicted effector loci and across the AC Sn4 contig23, reinforced the impact of the known ToxA, Tox1 and Tox3 effectors, and predicted 17 candidate effector loci with high levels of diversifying selection [31].

The recent updates to *P. nodorum* genomic resources enable consideration of the genomic landscape and sequence features which are relevant to pathogenicity or adaptation at the chromosome-scale, such as repeat-rich regions and mutation hotspots [26, 30, 32]. Long-read-based methods have significantly improved genome assembly of these previously challenging regions [12, 16, 18, 33, 34] and scaffold lengthscan be further improved with genome-finishing techniques including optical restriction [14, 35] or chromosome interaction mapping [36]. In fungal pathogens with “two-speed” genomes, repeat-rich regions typically accumulate mutations more rapidly than conserved gene-rich regions [26], leading to compartmentalisation of pathogen genomes into stable
GC-equilibrated regions and AT-rich ‘mutation hotspots’, which can include pathogenicity-associated ACs or ARs [30]. For pathogenicity loci not residing within ACs, growing evidence supports their frequent location in sub-telomeric mutation hotspots [37–39] which may also be ARs. The segregation bias of certain gene functions to the sub-telomere may be associated with the role of heterochromatin found at sub-telomere region in regulating gene expression during infection [39] and protection of the core genome from interspersion of sub-telomeric heterochromatin [40].

The presence or absence of effector genes, or ACs/ARs that contain them, can determine host/cultivar-specific virulence for several pathogen species [30]. Bioinformatic methods for effector prediction are usually of a reductive nature, which filter the complete gene set down to an candidate effector subset based upon multiple criteria [41]. These methods typically require effector gene annotations not to have been missed in the complete gene set (at either assembly or gene prediction steps), and directly benefit from the proper application of transcriptome data to gene annotation, which for gene-dense genomes like those of fungi can pose a technical challenge [42]. In this study, we present an updated chromosome-scale genome assembly for *P. nodorum* reference isolate Sn15, combining long-read data and optical mapping to arrive at a near complete telomere-to-telomere assembly of 23 chromosomes. Sn15 gene annotations have also been updated integrating new transcriptome data and extensive manual curation, which will ensure its reliability and ongoing utility as a model necrotroph. Insights from comparative genomics analysis is presented for comparisons of the Sn15 reference isolate versus the Sn4, Sn2000 and Sn79–1087 long-read assemblies, and an international panel of NGS-based assemblies for 28 other *Parastagonospora* isolates. This has highlighted mutation hotspots and locational biases across the 23 chromosomes of Sn15, including a 0.4 Mbp accessory chromosome and several telomeric ARs. New effector gene predictions for Sn15 are also provided, integrating the wealth of past data for Sn15 with new data including PAV and diversifying selection across the international pan-genome. These aggregated resources for *P. nodorum* Sn15 will offer novel research opportunities and serve as a useful tool to enhance ongoing efforts to breed for crop disease resistance.

Results

A chromosome-level reference genome assembly for *P. nodorum* Sn15

In order to complete the Sn15 assembly, a combination of long read sequencing using PacBio technology and optical mapping were used. PacBio DNA sequencing generated 368,822 raw reads of 50 bp to 41 Kbp in length at ~71X coverage. Self-correction resulted in 118,028 corrected reads, totalling 1.31 Gbp with an average length of 10 Kbp. Corrected reads were assembled into a draft assembly of 36 gapless contigs ranging from 3.5 Mbp to 37 Kbp, with a total length of 37.4 Mbp at 33.6X coverage. Only 844 corrected reads (0.7%) were not assembled. One of the 36 contigs corresponded to the previously published mitochondrial DNA sequence [GenBank: EU053989] and was discarded. An optical map produced 23 maps with an estimated total length of 39.26 Mbp (Supplementary Text 1). Thirty out of the 35 assembled contigs (36.88 Mbp) aligned to the 23 optical maps. The 5 contigs that did not align were short (38 to 120 Kbp, or 0.84% of the contig assembly) and highly repetitive, with no predicted genes. The curated scaffolds of contigs aligned to the 23 optical maps - subsequently referred to as ‘chromosomes’- were numbered in descending size order based on the physical lengths predicted by the optical map (Supplementary Table 5).

Fourteen chromosomes contained no gaps, and 8 gaps were added to join non-overlapping contigs within chromosomes 2, 3, 4, 6, 7, 10 and 20. Terminal ‘TTAGG’ tandem repeats indicating telomeres were observed at both ends of 21 chromosomes, with 2 having a single telomere. New repetitive regions comprised ~0.4% of the assembly. The new assembly had 286 fewer gaps than the previous version [20, 23] and there was a ~4 Kbp increase in the average length of AT-rich regions, a reduction of incompletely assembled AT-rich regions (~46) and an increase in fully assembled AT-rich regions (~33) (Supplementary Table 3).

A revised set of gene annotations aggregated from multiple sources of evidence, including new in planta RNA-seq, fungal-specific gene finding software and manual curation

An estimate of the representation of the core gene content in the updated Sn15 assembly via BUSCO (v5.1.2) indicated 99.1% completeness versus the “fungi” dataset (fungi_odb10, 2020-09-10). The combination of various gene prediction methods (see methods), incorporating recently published in vitro and in planta RNA-seq data [23, 43], fungal-specific gene prediction software, and manual curation, resulted in 16,431 predicted genes. This gene set was split into two subsets: a higher confidence set (Set A), and a lower confidence set to allow more sensitivity for subsequent pathogenicity gene predictions (Set B) (Fig. 1, Table 1A). Set A included 13,893 high confidence genes models with higher levels of support, whereas set B contained 2538 putative genes with either shorter coding sequence length or less RNA-seq support (Table 1B). Compared to the previously published annotation [20, 23], average gene length decreased by 70 bp and gene density increased by 2.8 genes per
Mbp (Table 1A). Set B annotations were on average length 4 times shorter than those of Set A and in 86% of cases were a single exon (Table 1A). Of the 16,341 genes, 9788 were informatively functionally annotated (i.e. a conserved domain), and 990 of these also had a predicted secretion signal peptide (Fig. 1). The predicted secretome comprised 1568 genes of which 257 (1.5% of total genes and 25.3% of the secretome) were effector candidates (Fig. 1, Table 1). Across the Sn15 genome, gene density was inversely correlated with density of repetitive DNA (Fig. 2), with genes distributed at a relatively even density (~450 Mbp) except for accessory chromosome 23 (AC23 which was gene sparse (~380 Mbp) (Fig. 2). A lower proportion (36.7%) of loci were assigned functional annotations within AC23, which was 13% less than average. The known necrotrophic effector genes ToxA, Tox1 and Tox3 were all located within sub-telomeric regions of chromosome 4, 10 and 11 respectively, with ToxA also notably residing in the middle of a large (~570 Kbp) repeat-rich region (Fig. 2).

**Comparative genomics**

In comparisons of the Sn15 genome to alternate isolates, the Sn15 genome exhibited multiple large PAV regions (Fig. 2, Supplementary Table 6, Supplementary Table 7). Prior pan-genome and in silico studies using the previously published Sn15 assembly as its reference genome had indicated scaffolds 44, 45, 50 and 51 as regions of the genome with PAVs [20, 23, 29] (Supplementary Table 8).

Scaffold 50 corresponded to a sub-telomeric region of chromosome 8 (Supplementary Table 8). New reports of additional variable regions derived from this study include regions of chromosomes 7, 8 and 10. Chromosome 7 contained a ~455 Kbp region that is potentially duplicated in some isolates, but is represented in single copy in the current Sn15 assembly. Chromosomes 8 and 10 contained ~88 Kbp and ~10 Kbp PAV regions respectively. The PAV on chromosome 10 contained no genes, and the PAV on chromosome 8 contained 27 genes (Supplementary Table 9) but did not contain any predicted effector candidates (Supplementary Table 4).

Former scaffolds 44 and 45 corresponded to the ~444 Kbp AC23 of this study (Supplementary Table 8). Pan-genome alignment of Sn15 chromosomes with other *P. nodorum* and *P. avenae* isolates indicated that chromosome 23 was absent in *P. avenae* and the non-aggressive *P. nodorum* isolate Sn79–1087 (Fig. 2), which suggested that it lacked genes required for viability and was an accessory chromosome. In contrast, the majority of other “core” chromosomes were well conserved across *Parastagonospora* spp. AC23 also exhibited higher overall levels of non-synonymous mutations indicating diversification across this population relative to the Sn15
reference isolate (Supplementary Table 10). However the mutation profile of AC23 contained two regions separated by a large repeat island – each side corresponding to scaffolds 44 and 45 of the previously Sn15 assembly [20, 23] - which exhibited distinctly different mutation rates (Fig. 2). Comparison of AC23 to other Sn15 chromosomes did not indicate that it had originated from duplication of core chromosomes (Supplementary Figure 1), however homologous (non-repetitive) regions in *Pyrenophora tritici-repentis* [14, 44] and *Bipolaris* spp. [28, 29] genomes tended to be located in sub-telomeric regions (Supplementary Figure 2).

The previous scaffold 51 corresponded to a ~74 kbp region within a repeat-rich sub-telomeric region of chromosome 4 (Supplementary Table 8), which also contained the effector gene *ToxA*. This sub-telomeric region had below average GC content, correspondingly high repeat content (~18.3% higher than the genome average), increased mutation density and less than half of the average gene density (Supplementary Table 6). The 9 predicted loci within this region had an average DN/D5 of 1.9, more than double the genome average (Supplementary Table 6). Alignment of this region between the Sn15 assembly presented in this study, and the long read assemblies of Sn4, Sn2000 and Sn79–1087, showed structural variations that may indicate that breakage-fusion bridge (BFB)-mediated rearrangements (distal translocations between chromosomes lacking telomere caps) may have occurred in one or more of these isolates (Supplementary Figure 3) [45]. Comparisons of this region to corresponding regions containing *ToxA* homologs in related species *Pyrenophora tritici-repentis* [14, 44], *Bipolaris maydis* [29] and *B. sorokiniana* [28], indicated further chromosome structure diversity. The sub-telomeric *ToxA* region of chromosome 4 in *P. nodorum* appeared to be consistent with *Bipolaris* spp. where it was also found in sub-telomeric locations. In contrast, the *P. tritici-repentis ToxA*-containing chromosome appeared to be a product of the breakage of the *P. nodorum* *ToxA* region, followed by chromosome fusions resulting this region being flanked by sequences corresponding to *P. nodorum* chromosomes 14 and 19 (Fig. 3).

**Discussion**

The chromosome-level assembly for *P. nodorum* reference isolate Sn15 improved detection of pathogenicity gene-rich regions

The new chromosome-level genome assembly of *P. nodorum* Sn15 created by this study has established the correct number of chromosomes for this pathogen, which was previously underestimated by PFGE to range from 14 to 19 [19], and is consistent with 22–23 observed in assemblies of other isolates [15, 31]. PFGE fragment resolution accuracy requires at least ~1% difference in chromosome size [46], meaning 6 out of the 23 assembled sequences were within a potentially unsolvable size range (Supplementary Table 5). The

| Table 1 | Summary of new gene annotations of *P. nodorum* reference isolate Sn15. A) Comparison of high-confidence Set A and low confidence Set B to previous annotation versions and B) summary of data supporting gene annotations |

difference in chromosome number between the two studies therefore is justified. This study also presents 21 out of 23 chromosomes with both telomeric ends and 14 gapless chromosomes. In addition, the new chromosome-level genome assembly for Sn15 was also supported by transcriptome data and manually curated gene annotations, and related bioinformatic resources for the *P. nodorum* Sn15 reference isolate were updated, enhancing these important resource for studying molecular host-pathogen interactions and for effector discovery [41, 47, 48].

Chromosome-level analysis of the genomic landscape can enable detection of compartmentalised mutation ‘hot spots’ that may contain pathogenicity loci - a commonly reported feature for “two-speed” genomes which have been broadly affected by transposon activity and

repeat-induced point mutation (RIP) [24, 26]. As genome assemblies have been improved towards chromosome-scale representation, there have also been several reports of pathogenicity genes within sub-telomeric locations in other pathosystems [15, 17, 37, 38, 40]. Thus, the new Sn15 assembly presented new opportunities to predict novel pathogenicity-related genes within the ‘two-speed’ regions that are repeat-rich or conditionally-dispensable [26, 30, 32]. Presumably, the apparent bias of pathogenicity gene locations within mini-chromosome or sub-telomeric regions could be associated with BFB formation [45] and mesosyntenic rearrangements [27, 32] between chromosome termini. Indeed, pan-genome comparisons indicated that the 0.4 Mbp AC23 was an accessory chromosome, with gene content relevant to pathogenicity (see below). The updated Sn15 assembly also highlighted additional regions not present in previous assembly versions, which comprised ~152 Kbp of repetitive DNA (0.4% of the genome) and 86,468 bp of non-repetitive DNA. While these represented a very small proportion of the genome, they may have special significance for plant pathology as they are more likely to contain effector or other pathogenicity genes. The relative placement of these regions in the genomic landscape was also important in assessing their likely roles in pathogenicity adaptation [26, 30, 32] as a parameter for effector prediction [41].

**Candidate effector genes were derived from extensive gene annotation data for P. nodorum Sn15**

Considerable efforts have been made across previous studies to ensure the reliability and ongoing applicability to plant pathology research of the annotated gene set for P. nodorum Sn15 [1, 20–23, 42], particularly for the purpose of effector and pathogenicity gene discovery. The revised Sn15 gene set includes a primary set of 13,893 genes (Set A) and a lower confidence set of 2538 (Set B) which was retained to enhance the sensitivity and capacity of effector gene predictions. The total number of predicted genes has increased since the previous annotation version [23], and is also higher than the currently reported average across the Ascomycota [49]. However we note general trends across all species, that while reducing assembly fragmentation can reduce the total number of predicted genes [50], the addition of significantly improved transcriptome data [51] or gene prediction methods [42] can increase this number. Functional annotations were assigned to 59.5% of predicted genes (Set A + B, excluding non-specific features e.g. coiled-coils, intrinsic disorder).

Across the whole genome, 257 effector candidate genes were predicted (Fig. 1, Supplementary Table 4), a number comparable to similar fungal pathogen genome surveys [41]. Effector candidate genes exhibited the typical features expected of effectors, including: secretion, low molecular weight, cysteine richness, diversifying selection, association with mutation hotspots, and where functional annotations were assigned these had a common pathogenicity-related theme (Supplementary Table 4). Secretion was predicted for 1558 genes (9.5% of Set A + B), of which 257 (16.5% of predicted secretome) were effector candidates and 12 were predicted to localise to the chloroplast (including the confirmed effector ToxA) (Supplementary Table 4). Effector candidate loci were typically found within either 5–10 or 20–25 Kbp of AT-rich regions, which was not the case across the whole gene set (Supplementary Table 4, Supplementary Table 11). This is consistent with reports of RIP and effector location bias within AT-rich mutation hotspots [26]. The ToxA locus was 4039 bp and Tox3 was 1860 bp from their nearest respective AT-rich regions. The Tox1 locus was located >200 Kbp from its nearest AT-rich region, however all 3 effector loci were also located within sub-telomeric regions (Fig. 2). This association between telomeres and effector-rich mutation hotspots is also reported in other pathogen species [30, 32]. Comparison of orthologs between the Australian reference isolate Sn15 and the US isolate Sn4 [15], indicated 14 out of the 17 previously published Sn4 candidate effectors were also predicted among the Sn15 candidates (Supplementary Table 12). These Sn4 candidates – which included Tox1 - were previously reported to exhibit diversifying selection that was specific to one of the 2 major US sub-populations [31].

**Functionally-redundant genes may be associated with potential pathogenic properties of accessory chromosome 23**

Surprisingly, AC23 which exhibited typical characteristics of ACs [15, 30, 31, 52] - and may correspond to anecdotal reports of a ~0.4 Mbp AC specific to P. nodorum wheat and barley-infecting isolates [53] - had a relatively low density of effector candidate loci (Supplementary Table 4, Supplementary Table 10). Six candidate effector loci were predicted on AC23 in a previous study [23], with two of these (SNOG_16226 and SNOG_16236) re-predicted (with ranked scores of 10 and 9 respectively) in the more stringent predictions of this study. AC23 also encoded multiple genes with other pathogenicity-related and/or redundant functions, which may indicate tandem duplications or multiple BFB events. These functions included: Ulp1 protease (SNOG_16274, SNOG_16214), RING/FYVE/PHD-type zinc finger proteins (SNOG_16310, SNOG_16333), valyl-trna synthase (SNOG_16268, SNOG_16213, SNOG_16211), and UstY1-like protein (mystoxin biosynthesis) (SNOG_16357) (Supplementary Table 13). Ulp1 protease is involved in the modification of SMT3, a
Homologs of C. fulvum ECP2, a necrosis in common domain in spider, insect and snake venoms

acyl bond between 2 phospholipids that releases arachidonic acid from phospholipase A2 - which cleaves sn-2

that disrupt cell membranes [65]. SNOG_00200 encodes a product similar to Alternaria alternata allergen 1 (AA1-like). The AA1-like family [66] contains the V. dahliae effector PevD1, which binds the host thaumatin PR5 [67]. SNOG_00182, SNOG_02182, and SNOG_16063 encode ribotoxins, which have a conserved sarcin/ricin loop (SRL) structure that cleaves specific sequences in the host rRNA, leading to ribosome inactivation and cell death by apoptosis [68]. SNOG_13722 encodes a cerato-platanin, which induces phytoalexin synthesis and causes necrosis [69]. SNOG_06012 encodes a protein similar to gamma crystallin/yeast killer toxin, which is a pore-forming cytotoxin [70]. SNOG_01218 encodes a subtilisin, a serine protease family that is frequently reported in fungi to promote virulence [71]. SNOG_03959 encodes a protein similar to a cyclophilin-like/peptidyl-prolyl cis-trans isomerase (PPIase) [72], which in humans is well known for interfering with the immune-suppressive drug cyclosporin A, but is widespread across eukaryotes and has been reported as virulence determinants in several fungi including: Leptosphaeria spp., Botrytis cinerea, Cryphonectria parasitica, Puccinia triticina, M. oryzae, and Lhelinus sulphurascens, as well as various oomycete species of the Phytophthora genus [73]. SNOG_08289 encodes a pectin/pectate lyase, which are reported in many fungi to promote virulence [74]. SNOG_11034 encodes a protein similar to Egh16, an appressorium-located virulence factor of Blumeria graminis f. sp. hordei with broadly conserved homologs across several pathogenic fungal species [75]. SNOG_15608 encodes a cutinase, which may be involved in host surface penetration [76]. SNOG_02399, SNOG_03334, SNOG_40970, SNOG_08150, SNOG_04779 all encode for proteins with lipid interacting domains. SNOG_11842 encodes a Hce2 effector homolog - which is named after Homologs of C. fulvum ECP2, a necrosis inducing effector. There are 3 defined classes of proteins with Hce2 domains, of which SNOG_11842 belongs to class I, the smallest and most common class [77]. Many of the above candidates with pathogenicity-related functional annotations are also expressed higher in planta (IP) relative to in vitro (IV) by a factor of 5, however the Tox3 IP:IV is only 2 indicating this lower values may also be relevant in host-pathogen interactions. A lower-ranked candidate (SNOG_06459) with a ranked score below 5 is also mentioned here as it encoded a cerato-ulmin homolog. Cerato-ulmin is a hydrophobin, which is not a functional class normally reported to be directly involved in pathogenicity, but has been reported as a potential virulence factor in dutch elm disease [78]. Its mode of action is not like a typical effector however, as its role appears to be to protect spores from desiccation, which leads to increased spore survivability and transmission.

ubiquitin-like protein of the SUMO family which suppresses MIF2 mutations. MIF2 is a centromere protein that regulates stability of di-centromeric mini-chromosomes in baker's yeast [54]. Its presence on AC23 is notable given that AC23 is a mini-chromosome and is therefore more likely to be unstable. Ust'Ya-like proteins are involved in the secondary metabolism synthesis of cyclic peptide mycotoxins including ustiloxin and cyclochlorotine [55], however the products of many remain unknown. FYVE domain zinc finger proteins reportedly may bind to phospholipid PI3P [56], which could potentially facilitate host cell uptake. The genes and functions listed above represent candidate pathogenicity loci residing on AC23 which are of high importance for further investigation.

A trove of effector and pathogenicity gene homologs were predicted among candidate effector-loci

We previously observed that the deletion of ToxA, 1 and 3 in P. nodorum SN15 resulted in a mutant that retained near-WT level of virulence on most commercially adopted wheat varieties [57, 58]. This suggested that SN15 that lacked ToxA, Tox1 and Tox3 may have produced undiscovered effectors or other virulence factors to functionally compensated for the loss of these major NE genes [59, 60]. In addition, biochemical and genetic characterisation of US P. nodorum isolates identified evidence of other NEs [5–11]. This prompted us to apply a bioinformatic approach to predict for NE candidates in the near-complete SN15 genome that are relevant to the Australian cereal industry. From the prediction analysis, ToxA, Tox1 and Tox3 ranked highly among the top 98 SN15 candidates with ranked scores of 5 and above (Supplementary Table 10). While remaining candidates are unconfirmed, among these we observed a wealth of assigned functions or matches strongly suggesting roles in pathogenicity. SNOG_13622 and SNOG_08876 encode for CFEM domain proteins, which have roles in iron acquisition and several of which have been reported with roles in virulence [61]. SNOG_42372 and SNOG_07772 encode for chitin-binding LysM domain proteins which offer protection from PTI in the host [62]. SNOG_07596 encodes a thaumatin-like protein, which when produced by host plants are pathogenesis-related (PR) proteins involved in defence, however fungal homologs have also been reported with roles in virulence [63]. SNOG_03746 encodes a knottin-like protein. Knottins are cytotoxins that are best represented by snake and arachnid venoms, with the first fungal report of a knottin in the poplar rust Melampsora larici-populina [64]. SNOG_30910 encodes a homolog to phospholipase A2 - which cleaves sn-2 acyl bond between 2 phospholipids that releases arachidonic acid and lysophosphatidic acid - and is also a common domain in spider, insect and snake venoms.
Multiple effector candidate loci were predicted to be laterally-transferred with other cereal-pathogenic fungal species

Of the 98 highly-ranked effector candidates, 11 showed a conservation pattern indicating potential lateral transfer when compared to a panel of whole gene sets of >150 fungal species (Supplementary Table 4) [79]. This included SNOG_16571 (ToxA), SNOG_20078 (ToxI), SNOG_13622 (CFEM domain), SNOG_15952 (ribotoxin-like), SNOG_00152, SNOG_01658, SNOG_20100, SNOG_08426, SNOG_07039, SNOG_00726, and SNOG_14618.

These had rare orthology relationships indicating potential lateral gene transfer (LGT) with Pyrenophora spp., Setosphaeria turcica, Alternaria brassicicola, Verticillum dahliae, Leptosphaeria maculans and Coccidioides immitis. Aside from SNOG_13622, SNOG_15952, and known effectors ToxA and ToxI, this group of effector candidates had no predicted functional annotations. As expected, SNOG_08981 (Tox3) was not included in this set and has so far been reported to have no known homologs.

Conclusions

The P. nodorum isolate Sn15 was the first representative of the class Dothideomycetes with a genomic survey report [1], and has since become an important reference and model necrotroph with a significant set of accumulated genomic, transcriptomic, proteomic and bioinformatic resources supporting its genome and gene data [15, 20–25, 31, 43]. This study updates these resources in the context of a chromosome-scale assembly, identifying genome features relevant to pathogenicity i.e. sub-telomeric regions, accessory chromosomes and mutations hotspots. This has provided genomic context to subsequent predictions of candidate genes encoding effectors and other pathogenicity factors. In contrast to the earliest Sn15 genome study, effector candidates were supported by a wealth of functional annotation and comparative genomics data indicating strong homology to known effectors and other pathogenicity genes. This study is an important step forward for the further characterisation of P. nodorum chromosome structure and its role in pathogenicity, particularly in highly mutable and potentially effector-rich regions of the genome including AC23. Additionally, the increased representation of repeat-rich regions and provision of curated gene annotations within them, is of high value to ongoing efforts to characterise and understand fungal effectors. We anticipate future studies will utilise the effector predictions provided in this study to confirm new novel P. nodorum effectors, and potentially discover a role for AC23 in promoting virulence.

Methods

Genome sequencing and assembly

Genomic DNA of P. nodorum (syn. Phaeosphaeria nodorum, Stagonospora nodorum, Leptosphaeria nodorum, Septoria nodorum) strain Sn15 [20] – originally isolated in Western Australia by the Dept. Primary Industries and Regional Development (DPIRD: Agriculture & Food) - was sequenced via Pacific Biosciences P5-C3 chemistry with 4 SMRT cells, at the Génome Québec Innovation Centre (McGill University, Montreal, QC, Canada). The longest 25% of reads were self-corrected and assembled using Canu v1.0 (~pacific, expected genome size 39 Mbp) [13]. Assembly base-calls were corrected with Pilon v1.16 [80] using Illumina reads [20] which were mapped to the assembly with Bowtie2 v2.3.3.1 [81]. Mitochondrial contigs assembled by the above methods were identical to a previously published Sn15 mtDNA [GenBank: EU053989] [1] therefore the old mtDNA record was not updated by this new assembly.

Optical maps were used to order and orient the Canu-assembled Sn15 contigs into a complete genome. Sn15 protoplasts were extracted from hyphae as per Solomon et al [82], which was adjusted to 1x10e8 with GMB (0.125 M EDTA pH 8.0, 0.9 M sorbitol) at 42 °C. Protoplasts were added 1:1 to 1% low melt agarose (SeaPlaque GTG in 2% sorbitol and 50 mM EDTA) and poured into Plug Mold (Bio-Rad Laboratories, Munich, Germany) and set at 4 °C for 30 min. The plug was added to 5 ml Proteinase K solution (1 mg/ml Proteinase K, 100 mM EDTA pH 8.0, 0.2% Na deoxycholate, 10 mM Tris pH 8.0 and 1% N-lauroyl sarcosine) and incubated at 50 °C overnight, then added to sterile wash buffer (20 mM Tris pH 8, 50 mM EDTA pH 8) for 4 h changing the solution every hour. Clean plugs were transferred into 0.5 M EDTA at 9.5 pH and stored at 4 °C until shipment at room temperature. High molecular weight DNA was extracted from protoplasts as per Syme et al [23] and digested with SpeI, resulting in 63,440 fragments with an average size of ~315 Kbp. Optical maps were generated and manually curated with MapSolver™ (OpGen, MD, USA). Contig joins were made by inserting a 100 bp unknown (N) gap. Where the optical map indicated contig mis-assemblies, potential breakpoints were inspected for a localised drop in aligned read coverage. Chromosome scaffolds were numbered in descending size order based on the estimated physical lengths derived from the optical map. Chromosome scaffolds were assessed by bwa-mem (0.7.17-r1188, –x pacbio) [85] via SAMtools [86] and BEDtools [87]. The assembled Sn15 chromosome scaffolds of this study were compared to previously published assembly versions (Supplementary
Table 1) [15, 23] with MUMmer 3.0 (nuclmer -max-match, show-cords) [88] and alignments were visualised with Dot [89]. The SN15 reference genome data is available under BioProject: PRJNA686477. The updated SN15 genome assembly is deposited under [Genome: GCA_016801405.1/ASM1680140v1] and [NUC: CP069023.1 - CP069045.1].

**Annotation of genome features**

Repetitive DNA regions within the Sn15 genome assembly were analysed by three methods. The presence and overall proportion of AT-rich regions were calculated with OcculterCut v1.1 [26]. Annotation of repeat regions was performed using RepeatMasker 4.0.6 (sensitive with OcculterCut v1.1 [26]. Annotation of repeat regions overall proportion of AT-rich regions were calculated likely were analysed by three methods. The presence and Repetitive DNA regions within the Sn15 genome assembly were identified by terminal Minscore = 180, MaxPeriod = 2000) [95]. Telomere repeats were predicted using Tandem Repeat Finder (Parameters: Minscore = 180, MaxPeriod = 2000) [94]. Telomere regions were identified by terminal “TTAGGG” tandem repeats [95].

Protein-coding gene loci were annotated incorporating multiple transcriptome datasets from previous studies [23, 43]. RNA-seq reads from a prior study [43] were trimmed with cutadapt v.9.1 (paired end mode, --quality-cutoff = 30, --minimum-length 25, -n 3) [96] and de-duplicated with khmer v2.0 and screed v0.9 (normalize-by-median.py, -C 30 -M 100e9) [97, 98]. Fungal RNA-seq reads were derived from a mixed in planta library during early infection (3 dpi) when known effectors are maximally expressed [60]. Fungal reads were separated from wheat sequences with BBsplit v36.11 (BBmap, Seal v36.11, -Xmx200g) [99] to screen against the *Triticum aestivum* assembly TGAC v1.30 (GCA_900067645.1) [100]. Filtered reads were mapped to the new Sn15 assembly with STAR v2.5.2b (align-Reads, --outsAMstrandField intronMotif --outFilterIntronMotifs) [101]. Transcript assembly was performed with Trinity v2.2.0 (--seqType fa --trinity_complete --full_cleanup --jaccard_clip) [102]. RNAseq reads were aligned to the SN15 assembly with TopHat v2.2.6.0 (defaults) [103]. Relative expression was quantified with Cufflinks [104] and Stringtie v1.3.3b (params -m 50 -B -e -p 8) [105].

A final set of gene annotations was generated by combining annotations from multiple sources. Initial transcriptome-based predictions were made with PASA v2.0.2 [106], incorporating: Trinity transcripts; open-reading frames generated with Transdecoder v2.0.1 [102]; CodingQuarry (CQ) v2.0 predictions based on TopHat outputs [42]; a second round of predictions generated using Coding-Quarry “Pathogen Mode” (CQPM) (A. testa, 2016) within regions between the initial CQ predictions. De novo prediction was performed with GeneMark-ES v4.32 (ES, --fungus) [107]. Previously published gene annotations for Sn15 were aligned to the new assembly with AAT r03052011 [108] using CDS features (--dds ‘-f 100 -i 20 -o 75 -p 70 -a 2000’ --filter ‘-c 10’ --gap2 ‘\* 1’) and protein sequences (--dps ‘-f 10 -i 30 -a 200’ --filter ‘-c 10’ --nap ‘\* 10’). All predicted gene annotations described above were assigned relative weight scores (AAT protein mapping 1, EST 5, AAT CDS mapping, GeneMark-ES 1, CQ/CQPM 10, transdecoder 10, PASA 9) and were then integrated into a single annotation set via EvidenceModeler (EVM) v1.1.1 [106]. Every locus of the EVM annotation set was manually curated using Webapollo [109] alongside supporting evidence from the various prediction methods described above, InterProScan domains aligned to the genome [110], aligned RNAseq reads [23, 43] and annotated repeat features (see above). New loci were manually annotated within intergenic regions if supported by RNAseq alignments. The resulting set of manually curated annotations were filtered (Table 2) for either: 1) orthologous best hit to the 13,690 gene models from the previously published annotation [20, 23] or; 2) coding regions (CDS) of >300 bp in length and with RNAseq read coverage of >50 fragments per kilobase of transcripts per million mapped reads (FPKM). This filtered set of manually curated genes is subsequently referred to as the primary gene set (Set A). The remaining predictions that failed this filter were retained as a secondary gene set (Set B) if CDS length was >90 bp and RNAseq depth was >5 FPKM or if homologous to a previously annotated gene [1, 20, 23]. To be consistent with previous publications on *P. nodorum* genomics, in this study gene annotations corresponding to loci that had been numbered in previous studies [1, 20, 23] retained their previous locus number despite non-sequential order along the new assembly. New annotations not corresponding to previously annotated loci were numbered from SNOG_40000 onwards.

Various software and databases were used to assign functional annotations for both gene sets (A and B). OcculterCut v1.1 [26] predicted AT-rich regions and distances to the nearest AT-rich region for each locus. InterProScan (5.27–66.0) [110] was used to generate a broad range of functional annotations (InterPro, Pfam, Gene3D, Superfamily, MobiDB). PHylbase v4.2 [48] was searched to assign homology to known effectors. SignalP
v4 [111], was used to predict extracellular secretion, EffectorP v2.0 [47] was used to predict effector functions, and Localizer v1.0 (–e mode) [112] was used to predict potential host-cell sub-cellular localisation. The dbCAN r07/20/2017 [113] and AntiFam r3.0 databases were both searched using hmmsearch (–cut_ga) [114] to predict carbohydrate-active enzymes (CAZymes) and pseudogenes respectively.

### Comparative pan-genomics

The new Sn15 genome reference was compared with draft assemblies of 18 *P. nodorum* isolates [20, 23] and 10 *P. avenae* isolates [BioProject: PRJNA476481], as well as long-read assemblies of 3 isolates of *P. nodorum*: Sn79–1087 [BioProject: PRJNA398070; Genome: GCA_002267025.1], Sn4 [BioProject: PRJNA398070; Genome: GCA_002267045.1] and Sn2000 [BioProject: PRJNA398070; Genome: GCA_002267005.1] [15, 31] (Supplementary Table 1). Whole-genome alignments and variant calling was performed via MUMmer v3 (nucmer –max-target Table 1). Whole-genome alignments and variant calling was performed via MUMmer v3 (nucmer --max-target 8070; Genome: GCA_002267005.1) [15, 31] (Supplementary Table 4) used to assign scores associated gene or protein properties, as has been reported in previous studies [20, 23]. In this study the features (Supplementary Table 4) used to assign scores were: predicted secretion by SignalP 4.1 [111] (1 point); molecular weight < 30 kDa (1 point); %cysteines > 4% (1 point); DN:DS > 1.5 (1 point); distance of 0–5 from an AT-rich region as predicted by OcculterCut [26] (1 point); EffectorP [47] score > 0.9 (1 point); an *in planta* to in vitro differential expression ratio (IP:IV) > 5 (2 points) or < 1 (–2 points); sub-telomeric location within genome (within 500 Kbp of sequence end, 2 points); presence (~3 points) or absence (3 points) of ortholog in low-virulence isolate Sn79–1087; presence of ortholog predicted as an effector candidate in US isolate Sn4 [31] (3 points); assigned an effector/toxin-like functional annotation (3 points) and; predicted lateral-gene transfer event with a fungal pathogen species [79] (3 points).

### Prediction of necrotrophic effector (NE) candidate gene loci

Putative effector genes were predicted based on the ranking of cumulative scores assigned from effector-associated gene or protein properties, as has been reported in previous studies [20, 23]. In this study the features (Supplementary Table 4) used to assign scores

---

**Table 2** Criteria used to predict the primary gene prediction set (Set A) for *P. nodorum* Sn15, and the secondary set (Set B) which contains low-confidence gene predictions for the purpose of extracting a small proportion of strong effector candidates.

| Criteria                  | Set A (high confidence)                                                                 | Set B (putative)                                                                 |
|---------------------------|---------------------------------------------------------------------------------------|---------------------------------------------------------------------------------|
| CDS length                | > 300 bp / > 100 aa                                                                 | (> 90 bp / > 30 aa                                                             |
| Gene expression           | AND                                                                                   | AND                                                                             |
| Orthology/Homology        | > 50 FPKM                                                                             | > 5 FPKM                                                                        |
| Orthology (reciprocal best hit) to previous annotation | (20, 23)                                                             | Homology to previous annotation (20, 23)                                        |

Acknowledgements

We thank Prof. Richard Oliver for his expertise and guidance, and Ms. Julie Lawrence for her assistance with laboratory work relating to optical mapping.

Authors’ contributions

KCT and JKH conceived the experiment and supervised the research. SB performed the majority of bioinformatics analysis, with assistance from DABI and JKH. SB and JKH drafted the manuscript and JKH, HTP and KCT substantially revised the manuscript. All authors read and approved the manuscript.

Funding

This study was supported by the Centre for Crop and Disease Management, a joint initiative of Curtin University and the Grains Research and Development Corporation (Research Grant CUR00023). This research was undertaken with the assistance of resources and services from the Pawsey Supercomputing Centre and the National Computational Infrastructure (NCI), which is supported by the Australian Government (Research Grant Y95).

Availability of data and materials

The Sn15 reference genome and protein data is available under BioProject: PRJNA686477. The updated Sn15 genome assembly sequence consisting of 23 chromosomes is deposited under (Genome: GCA_016801405.1/

ASM1680140v1; NUC: CP069023.1 - CP069045.1). *P. nodorum* Sn15 transcriptome data was previously deposited under BioProject:PRJNA632579. Alternate isolate data for *P. nodorum* and *P. avenae* was previously deposited under BioProject:PRJNA47648. Alternate reference isolate data was obtained for Sn79–1087 from BioProject:PRJNA398070 / GCA_002267005.1, for Sn4 from BioProject:PRJNA398070 / GCA_002267005.1, and for Sn2001 from BioProject:PRJNA398070 / GCA_002267005.1.
