Abstract

The desirability of evaluating the effective potential in field theories near a phase transition has been recognized in a number of different areas. We show that recent Monte Carlo simulations for the probability distribution for the order parameter in an equilibrium Ising system, when combined with low-order renormalization group results for an ordinary $\phi^4$ system, can be used to extract the effective potential. All scaling features are included in the process.

I. INTRODUCTION

In the realm of statistical physics, as well as in quantum field theory, the need for non-perturbative approaches to study the vicinity of a phase transition has long been appreciated. Results of recent simulations [1–4] show that the form of the effective potential for a variety of systems can be determined using Monte Carlo methods. Such methods have also been applied to the study of the electroweak phase transition via lattice Monte Carlo methods [5]. Additional continuum limit work has recently been performed on a $\lambda \phi^4$ theory in three-dimensions [6]. Extracting the effective potential provides one with an additional window onto the equilibrium – and possibly the dynamical – behavior of a system near and at its critical point. One use of Monte Carlo methods is to test scaling forms based on the Renormalization Group. A second is to explore the equilibrium behavior associated with such phenomena as two-phase coexistence and broken continuous symmetry.

Binder [7] and more recently Tsypin [1] and Chen and Dohm [8] have utilized Monte Carlo and binning techniques to generate probability distributions of the order parameter of an $O(1)$ (Ising-like) system in the vicinity of its critical point. In Tsypin’s work data were generated at a single temperature, and over a range of symmetry-breaking fields in order to explore the full scaling domain. Above the critical temperature the distribution was found to be consistent with a low-order polynomial form for the effective potential, which, as discussed below, is essentially the logarithm of the probability distribution. The results of simulations were most closely fit when the effective potential was terminated at the sixth order. The standard quartic Ginzburg-Landau form for the effective potential failed to produce an adequate fit for any choice of coefficients, and the addition of eighth and higher order terms did not materially improve the agreement between the fitting form and the results of simulations.

This remarkable set of results persists below the critical temperature [2]. Here, it was found that a sixth-order polynomial form for the effective potential leads to an outstanding match to the results of simulations. In this case the best-fit effective potential was found to
contain a *negative* quartic term. An additional feature of Tsypin’s fitting form is a prefactor, proportional to the square root of the second derivative of the effective potential.

It is reasonable to ask whether or not the data are consistent with a scaling form for the effective potential. In fact, the nature of the polynomial strongly suggests a form incorporating thermodynamic scaling with exponents appropriate to the Ising model. The rationale for this will be explored in more depth in subsequent sections.

It should be noted that the renormalization group has been utilized previously to generate order parameter distributions in the vicinity of the critical point [4,8,9]. The principal novelty in this paper is the attempt to produce a unified form for the order parameter distribution that fits data above, below and at the critical point. It is found that the inclusion of the prefactor mentioned above leads for excellent agreement with data based on Monte Carlo simulations. The prefactor does not play an important role in the fitting of a scaling form to the order parameter distribution in the high and low temperature phases. However, this finite size correction is essential to the construction of a high-precision fit to data at the critical point.

Checks on the quality of the fit include comparisons of a universal ratio of moments of the distribution with values in the literature determined by a variety of alternative techniques, and comparison between our optimum fit value of the fourth order coupling $u$ with a variety of other determinations of that quantity. These checks are very encouraging. It appears that a scaling form based on renormalized mean field theory agrees to a high degree of accuracy with published results. On this basis, one has confidence that an equation of state constructed in a similar manner from renormalized mean field theory will accurately describe systems in the $O(1)$, or Ising model, universality class.

The remainder of this paper is laid out as follows. In the next section the effective potential is defined and a phenomenological scaling description is presented. In Sec. III a renormalization group derivation of the scaling form is given, and in the following section the “prefactor” is discussed. In Sec. V finite size effects are addressed, while Sec. VI assesses the success of the scaling form of the effective potential as a fit to Tsypin’s Monte Carlo
simulations. Sec. VII is devoted to concluding remarks. An Appendix contains a discussion of the effect of the prefactor on an important universal quantity.

II. SCALING CONSIDERATIONS

We imagine a scalar (Ising-like) system described by order parameter, \( \phi \) and ordering field, \( h \), in equilibrium at temperature \( T \). If the system is described by Hamiltonian \( H(\phi) \) the constrained (reduced) free energy, \( F(T, h; M) \), is given by

\[
Z = \exp \left[ -F(t, h; M) \right] = \int D\phi \delta (M - I(\phi)) \exp \left[ -H(\phi)/T \right],
\]

where \( I(\phi) \equiv \Omega^{-1} \int \phi \, d^d x \) is the average order in configuration \( \{ \phi \} \), \( \Omega \) represents the volume of the system, and \( d \) is the dimensionality. The effective potential \( H \), is usually defined as

\[
Z = \exp(-H)
\]

which identifies it with the constrained free energy. According to standard scaling notions, when the linear extent, \( L \), of the system is sufficiently great, the effective potential, \( H \), of an \( O(1) \) system will have the form

\[
H(t, h, M) = L^d |M|^{2d/(d-2+\eta)} F \left( t |M|^{-2/\nu(d-2+\eta)} , h |M|^{-(d+2-\eta)/(d-2+\eta)} \right) .
\]

The parameter \( t \) is the reduced temperature, \( t = (T - T_c)/T_c \), where \( T_c \) is the critical temperature, and the ordering, or symmetry-breaking, field \( h \) has been introduced above. The quantity \( L \) is a characteristic linear extent of the system, and \( d \) is its spatial dimensionality. The exponents \( \nu \) and \( \eta \) appear in the (unconstrained) two-point correlation function

\[
C \left( \vec{r} - \vec{r}', t, h \right) ,
\]

\[
C \left( \vec{R}, t, h \right) = |\vec{R}|^{-(d-2+\eta)} \mathcal{C} \left( |\vec{R}| t^\nu , h t^{\nu(d+2-\eta)/2} \right) .
\]

All thermodynamic exponents follow from the two correlation function exponents, \( \nu \) and \( \eta \), given the standard scaling and hyperscaling relations [10]. When the spatial dimensionality is \( d = 3 \), the critical exponents are [11]
\[ \nu = 0.63 \pm 0.002 \quad (2.5) \]

\[ \eta = 0.037 \pm 0.001 \quad (2.6) \]

An immediate consequence of expression (2.3) is that the effective potential at the critical point \((t = h = 0)\) has the form

\[ H_{\text{critical}} \propto L^d |M|^{2d/(d-2+\eta)} = L^d |M|^{\approx 5.7} . \quad (2.7) \]

It is reasonable to expect that, within the scaling regime, at low enough reduced temperature and ordering field, and for appropriate values of the order parameter (that is, if the order parameter controls the decay of correlations) the effective potential will behave in the same way. If one attempts to approximate the effective potential by a polynomial in the order parameter, \(M\), the “best” one will, most likely, not have terms that go beyond sixth order. Interestingly, this is precisely the result of Tsypin’s unbiased attempt to fit his simulation data to a polynomial effective potential: A fourth order, Ginzburg-Landau form fails to adequately represent the data, while the coefficients of terms beyond sixth order are so small as to cast doubt on their appearance in the true effective potential. This result holds both above and below the critical temperature—that is, whether the system is in the disordered or the ordered state.

Now, the form (2.3) is expected to apply only when the order parameter \(M\) lies at – or close to – the value which minimizes the free energy at fixed \(t, h\). In particular, there are known difficulties in applying the above scaling form (2.3) to the case of a system in the coexistence region, which impinge directly on the scaling regime. The equilibrium state within the coexistence regime will generally involve one or more interfacial regions separating two homogeneous thermodynamic phases. Because of this, the scaling form, which is hypothesized for a single homogeneous phase, does not necessarily do an adequate job of describing the behavior of a system in which two different phases coexist. On the other hand, a scaling form ought to predict with great accuracy the dependence of thermodynamic functions on temperature and ordering field as these fields approach the coexistence line, that is, at the phase boundary for two-phase coexistence.
There is one more consequence of scaling that is worthy of note. The scaling form in Eq. (2.3) together with correlation function scaling implies the following form for the free energy [12,13]

\[ H = \hat{G} \left( M \xi^{(d-2+\eta)/2}, h \xi^{(d+2-\eta)/2}, t \xi^{1/\nu}, L \xi^{-1} \right) \]

\[ = \hat{G} \left( M |t|^{-\nu(d-2+\eta)/2}, h |t|^{-\nu(d+2-\eta)/2}, L |t|^{\nu}, t \right) . \] (2.8)

In the first line of Eq. (2.8) the quantity \( \xi \) is the bulk correlation length at \( h = 0 \).

**III. RENORMALIZATION-GROUP BASED FORM FOR THE EFFECTIVE POTENTIAL**

The general form in Eq. (2.3) restricts, but does not specify, the detailed dependence of the effective potential \( H \) on \( t \) and \( h \). Other considerations are required for an explicit evaluation. One candidate form is based on the Renormalization Group, particularly the field-theoretical expansion in \( \epsilon = 4 - d \), where, as above, \( d \) is the spatial dimensionality of the system. We consider a standard \( \phi^4 \) Hamiltonian

\[ -\frac{H}{T} = \int \frac{1}{2} \left( (\nabla \phi)^2 + r \phi^2 + u \phi^4 \right) d^d x . \] (3.1)

At lowest non-trivial order in \( \epsilon \), the effective potential has the form [14]

\[ \mathcal{H}(M, t, h) = e^{-t^*} \left[ \frac{1}{2} t e^{(1/\nu)t^*} M e^{(d-2+\eta)t^*} + \frac{u}{4} M^2 e^{2(d-2+\eta)t^*} - h M e^{t^*} \right] . \] (3.2)

This approximate effective potential is at the level of a renormalized Ginzburg-Landau free energy, and is hence equivalent to “renormalized mean-field theory”. The renormalization, indeed the full effect of the Renormalization Group trajectories, resides in the quantity \( e^{t^*} \) which is equivalent to the “block spin” size. This key quantity may be determined via

\[ t e^{(1/\nu)t^*} + 3u M^2 e^{(d-2+\eta)t^*} = 1 . \] (3.3)

The effective potential described by Eqs. (3.2) and (3.3) is fully consistent with the scaling hypotheses embodied in Eq. (2.3). It is is completely determined once the coupling
constant $u$ has been set, along with “metrical” factors associated with the scales of $h$ and $t$. The inclusion of higher order, loop expansion contributions leads to modifications of the effective potential, so, on the face of it, there is no reason to expect that (3.2) will be exact. However, given that it is entirely consistent with critical point scaling, that it embodies the full RG trajectories, and that it represents the leading order contribution in a systematic Renormalization Group expansion for the free energy, it seems at least a plausible “zeroth order” candidate for the critical effective potential. This optimism is bolstered by other situations in which “renormalized mean-field theory” provides surprisingly good numerical results when applied in three dimensions. [15]

IV. THE PREFACCTOR

In this section we discuss the prefactor introduced by Binder [16] and used by Tsypin in fitting Ising simulations [1,2]. A variety of arguments have been advanced for the existence of this term. Here we introduce additional justification for the prefactor.

Suppose we allow spatial variations of the order parameter around the globally constrained value $M$ in the form $M + \sigma(\vec{k})$. Note that $\langle \sigma(\vec{k}) \rangle = 0$. Neglecting terms of greater than quadratic order in the $\sigma(\vec{k})$’s, the dependence of the effective Hamiltonian on the $\sigma(\vec{k})$’s at gaussian order will be

$$H_{\text{gauss}}[\sigma(\vec{k})] = \sum_{\vec{k} \neq 0} \left[ \frac{1}{2} \left| \nabla \sigma(\vec{k}) \right|^2 + \frac{1}{2} H''(\vec{k}) \sigma(\vec{k}) \sigma(-\vec{k}) \right].$$

(4.1)

The term $H''$ is the second derivative with respect to the order parameter $M$ of the effective potential $H$ at renormalized mean field level discussed above. As noted the sum excludes the $\vec{k} = 0$ mode of the order parameter fluctuations. Integration over the $\sigma(\vec{k})$’s yields the following “gaussian” correction to the effective potential

$$\sum_{\vec{k} \neq 0} \frac{1}{2} \ln \left( \frac{H'' + k^2}{2\pi} \right) \to \frac{\Omega}{(2\pi)^d} \int d^d k \frac{1}{2} \ln \left( \frac{H'' + k^2}{2\pi} \right) - \frac{1}{2} \ln \left( \frac{H''}{2\pi} \right).$$

(4.2)

As above $\Omega$ is the spatial volume of the system. The last term on the right hand side of Eq. (4.2) is the leading order difference between the sum on the left hand side and its asymptotic
limit as the integral on the right. This term can be thought of as a finite size correction to the extensive result in the limit, \( \Omega \to \infty \). A general feature of the prefactor that will prove to be of some use shortly is its connection with the renormalized mean-field susceptibility, \( \chi \). It is straightforward to verify that the second derivative of the effective potential with respect to the order parameter is inversely related to the susceptibility, i.e.,

\[
\mathcal{H}''(M) = \frac{1}{\chi(M)}.
\]  

(4.3)

When the effective potential displays the effects of critical fluctuations, the derivation above acquires modifications, specifically the inclusion of counter-terms in a full renormalization group treatment. Most of the steps leading to this finite size correction are as displayed above. The final result preserves the relationship between the prefactor and the isothermal susceptibility implied by the above equation. Specifically, the new prefactor has the form

\[
\sqrt{\frac{\mathcal{H}''}{2\pi}} = \frac{1}{\sqrt{2\pi\chi}}.
\]  

(4.4)

At the level of renormalized mean-field theory, one can write for the susceptibility

\[
\chi = e^{(2-\eta)\ell^*} = e^{\gamma\ell^*/\nu},
\]  

(4.5)

where \( \gamma \) is the critical exponent for the isothermal Susceptibility \( (\chi \propto |t|^{-\gamma}) \). As noted previously, the quantity \( \ell^* \) is determined by Eq. (3.3).

There is a more general argument for the existence of the prefactor. This argument is based on the “infinitesimal” momentum shell version of the Renormalization Group used in the calculation of the partition function of the Ginzburg-Landau-Wilson model [18]. In this approach, modes at the surface of a shrinking Brillouin zone are integrated out. The contributions to the free energy have a gaussian-like form. The key contribution to the net free energy is

\[
\frac{1}{2} \sum_k \log \left[ \Sigma_k + k^2 \right]
\]  

(4.6)

In expression (4.6), the self energy term \( \Sigma_k \) contains the effects of fluctuations whose wave vectors exceed \( k \) in magnitude. If the uniform mode is singled out, the sum in (4.6) is carried
out over all non-zero $k$’s. The one term that does not contribute to the free energy is, thus, equal to

$$\frac{1}{2} \log [\Sigma_0]$$

(4.7)

In this term the restriction on the momenta of the fluctuations contributing to $\Sigma_0$ no longer differentiates the quantity from the standard self energy, $\Sigma$. Standard arguments suffice to establish the connection between the the susceptibility and the self energy. If the $k = 0$ term is added to the sum in Eq. (4.6), we end up with a sum over all $k$ that constitutes the leading order bulk contribution to the effective potential. It is then necessary to perform a subtraction leading to a term in the exponent of the form $1/2 \log [\Sigma_0] = \ln \sqrt{\chi}$. That the “subtracted” term appears in the exponent with a positive sign reflects the fact that the partition function is the exponential of minus the free energy.

V. FINITE SIZE EFFECTS

There are other finite size effects. For example, there is a limit on the maximum possible size of a block spin in the renormalization procedure. This limit appears as a modification of Eq. (3.3). A limit on the block spin size, and hence the quantity $\ell^*$, is enforced if Eq. (3.3) is modified so as to ensure that the size of the block spin does not exceed the dimensions of the system. The new requirement on $\ell^*$ is

$$te^{(1/\nu)\ell^*} + 3uM^2 e^{(d-2+\eta)\ell^*} + \left(\frac{c}{L}\right)^2 e^{2\ell^*} = 1.$$  

(5.1)

The quantity $c$ is a number of order unity. In principle, the results of a calculation will not depend on the specific value of $c$, as the value of $\ell^*$ is a detail of the renormalization group procedure, which has no effect on the final result [14]. In practice, the results that follow from the use of Eq. (5.1) depend sensitively on the choice of the parameter $c$. In the work reported here, this quantity thus acquires the status of a fitting metrical parameter connecting the lattice size in the Ising simulations to the length parameter $L$ in the renormalization group approach.
VI. COMPARISON WITH DATA

The effective potential (3.2) is now compared to the results of the Ising model simulations performed by Tsypin [1–3]. Four data sets from Tsypin’s simulations are fit, one in the ordered phase ($\beta_o = 0.2227$), one in the disordered ($\beta_d = 0.22055$) and two at the critical temperature $T = T_c; (\beta_c = 0.22165)$. The data in the disordered phase are gathered in a Monte Carlo investigation of the order parameter distribution of a system of $58^3$ Ising spins. In the case of the ordered phase, the simulations were performed on a system of $74^3$ spins, while lattices of $16^3$ and $32^3$ were used for the simulations at criticality. The data are fit with the renormalized mean-field approximation Eq. (3.2) including the prefactor. The fitting procedure includes the use of the restriction on $\ell^*$ obtained by solving the transcendental equation, (5.1). The overall normalization is set such that the area under our curve matches that of Tsypin’s histograms.

Our fitting procedure utilizes a grid-search minimization of the $\chi^2(\vec{\alpha})$ merit function.

$$\chi^2(\vec{\alpha}) = \frac{1}{D} \sum_i \frac{(y(x_i; \vec{\alpha}) - d_i)^2}{\sigma_i^2} \quad (6.1)$$

The parameters $\{\alpha_j\}$ for the zeroth-order fit are $t$, $u$ and $c$ that appear in (3.2) and (5.1). Technically, this expression is the reduced $\chi^2$ since we divide by the number of degrees of freedom, $D$. $D$ is the number of data bins less the number of free parameters. The errors $\sigma_i$ were assumed to be of Gaussian order; i.e. $\sigma_i^2 = y(x_i; \vec{\alpha})$. This assumption is conservative since the $\chi^2$ is less than the expected result, which should be approximately unity.

As an initial effort to minimize $\chi^2$, a blind fit is performed across all the histograms of a given data set (e.g., in the disordered phase the seven histograms corresponding to the seven different values of the external field $h$). See Table I. In this blind fit each bin of each histogram is treated with the same weight. This procedure certainly leads to an unbiased minimization of $\chi^2$, but further fine-tuning is required as explained below.

It is important to note the similarity between the values of $u$ in both temperature regimes. In zeroth-order approximation we find $u_d = u_o = 0.231$ for the disordered and ordered
phases, respectively. This is quite significant in that Landau-Ginzburg theory dictates that the fourth-order coupling be the same everywhere. Also note that the value of $t$ that best fits the data from the critical simulations is indeed zero, as expected. We do observe one anomaly in the best fit values of the reduced temperature in the ordered and disordered phases, however. Namely, if we compare the ratio of the temperatures we obtain

$$\frac{t_d}{-t_o} = 0.873$$

while from Tsypin’s simulation we have

$$\frac{t_d}{-t_o} = -\frac{\beta_d - \beta_c}{\beta_o - \beta_c} = 1.05.$$ 

This is unfortunate as we expect this ratio to be the same in the simulations and our fit even though the temperatures themselves need not be.

An additional comment needs to be made for the fitting of the ordered phase data. Notice that in the $h = 0$ histogram we have removed the data lying to the left of the peak. Attempts to fit the data in that regime did not produce satisfactory results. We attribute this failure to the fact that a single renormalized Ginzburg-Landau form (such as Eq. (3.2)) is inappropriate to the region of two-phase coexistence.

One expects that the scaling form for the free energy (combined with the prefactor) should provide a reasonable approximation to the free energy in all temperature regimes using a single value of $u$ and $c$. To this end, we search for a set of parameters that minimize the $\chi^2$ for all data sets. The most effective strategy for accomplishing this task is to first determine a range of parameters $u$ and $c$ that fit the $t = 0$ data. These bounds are then used for a three parameter fit in the $t > 0$ and $t < 0$ phases which yields final values of $t$, $u$ and $c$. It should be noted that a significant amount of “tweaking” of the parameters is necessary in addition to the blind minimization of the $\chi^2$. These values are tabulated in II and the resulting probability densities are plotted against Tsypin’s data in the three temperature regimes. The plots are displayed in Figures 1 - 3. It is interesting to note that the ratio of temperatures discussed above is now
\[
\frac{t_d}{-t_o} = 1.06
\]

which is within one percent of Tsypin’s value.

To further evaluate our scaling form we also calculate the universal quantity [19,7]

\[
\Gamma_4 = \frac{\langle M^4 \rangle}{\langle M^2 \rangle^2} - 3 \tag{6.2}
\]

The values of \( \Gamma_4 \) from our calculations compared to other sources are tabulated in III.

As a final check on our results, we compare our best fit value of the renormalized coupling constant \( u \) with results obtained by other methods. A variety of techniques have been utilized to determine this universal quantity, including the \( \epsilon \) expansion [21], high order loop expansions in three dimensions [22–24], Monte Carlo simulations and high temperature series [25]. Recently reported values of the renormalized fourth order coupling constant range from 0.233 [23] to 0.236 [22]. This is to be compared with our optimum global fit \( u = 0.228 \); see Table II. Given that no attempt twas made to match previously determined values of the renormalized fourth order coupling in our fitting procedure, the quality of agreement can be described as, at the very least, encouraging.
TABLES

**TABLE I.** The values of fitted parameters $t$, $u$ and $c$ obtained from the blind fits for four different data sets. The stated errors are 68% confidence limits; i.e. one standard deviation.

VII. CONCLUDING REMARKS

We arrive at the conclusion that a low order scaling form provides an excellent fit to the order parameter distribution both quite near the three-dimensional Ising model critical point and exactly at criticality. Our approximant, while at the lowest nontrivial order in the interdimensional $\epsilon$ expansion, nonetheless includes full renormalization group flows for the relevant variables and thus has critical point (hyper-)scaling built in. The scaling result that at criticality $H \sim |M|^{2d/(d-2+\eta)}$, where $2d/(d-2+\eta) \sim 5.7$ is in close agreement with Tsypin’s [2,1] polynomial fit. That this ought to be so follows from straightforward scaling arguments.

The fitting parameters used were the nonuniversal metrical factors for the reduced temperature, $t$, the fourth order coupling constant $u$ and the parameter $c$, which controls the effects of finite size on the determination of the quantity $\ell^*$ through the relationship Eq. (5.1). This is certainly fewer than allowed; the $\phi^4$ model and the Ising model are presumably in the same universality class, but are not identical. We also took the coupling $u$ to be constant. However, there is no reason to believe that the Ising model at criticality is at its fixed point for coupling constants. Hence, corrections to scaling should certainly be allowed, which in practice would mean the renormalization group flow for the fourth-order coupling $u(\ell)$ could be included. We have chosen not to do so in order to minimize the number of free parameters.

The prefactor used by Binder [16] and Tsypin [1,2] is discussed in Section IV within the setting of a renormalization group calculation. While this prefactor has only limited effect on the quality of fits in the high and low temperature phases, it plays a crucial role at the critical point. This issue is discussed in more depth in the Appendix, where the influence of the prefactor on the universal ratio $\Gamma_4$ is also explored.

The fact that a low-order-in-$\epsilon$ expression for the renormalized free energy of the Ising system reproduces simulation data to such a high degree of accuracy has encouraging implications with respect to the derivation of an equation of state applicable to an $O(1)$ system
in the immediate vicinity of a critical point. In addition, there is every reason to be hopeful that low order corrections to the zero loop expression utilized in this work will allow for an even higher precision fit to data.

ACKNOWLEDGEMENTS

D.J. is grateful to the National Science Foundation for support of this work under DMR92-17935. He also thanks D. Boyanovsky for his interest and helpful comments. We are especially grateful to Dr. M. Tsypin for bringing this problem to our attention, for providing his simulation data and for useful comments throughout the progress of this work. W.L. acknowledges useful conversations with Professor R. Cousins. J.R. acknowledges the support of NASA and thanks C. Borg and V. Dohm for highly enlightening comments.

APPENDIX A: EFFECT OF THE PREFACTOR ON $\Gamma_4$

The prefactor represents a finite size correction to the free energy. To see that this is so, it suffices to exponentiate the prefactor. The contribution of the prefactor to the free energy is nominally independent of the size of the system, while the leading order terms scale as the system’s volume. Clearly, in the thermodynamic limit, the prefactor is swamped by those terms. Nevertheless, the prefactor cannot be ignored, even as the volume approaches infinity. That this is so is evident when one plots out the order parameter distribution at the critical point. Given Eq. (2.3), neglect of the prefactor leads to an order parameter distribution at the critical point $(t = 0, h = 0)$ that has the following form

$$P(M) \propto e^{-ALd|M|^{2d/(d-2+\eta)}}.$$ \hspace{1cm} (A1)

Such a distribution does not manifest one important feature of the critical point order parameter distribution, and that is a depression in the in the neighborhood of $M = 0$. The absence of this feature has an effect on the fit to data, and in addition, on the quantity $\Gamma_4$, defined in Eq. (6.2). As an indication of the importance of the prefactor on this universal ratio, we first calculate its value in the absence of this contribution. We make use of the general relationship

$$\int_0^\infty M^2 e^{-AM2d/(d-2+\eta)} = A^{-(p+1)2d/(d-2+\eta)} \frac{d-2+\eta}{2d} \int_0^\infty y^{(p+1)(d-2+\eta)/2d} e^{-y} dy = \frac{d-2+\eta}{2d} A^{-(p+1)2d/(d-2+\eta)} \Gamma \left( \frac{(p+1)(d-2+\eta)}{2d} \right),$$ \hspace{1cm} (A2)

where the function $\Gamma$ is the standard gamma function. The universal combination in Eq. (6.2) is, then, equal to

$$\frac{\Gamma \left( \frac{5(d-2+\eta)}{2d} \right) \Gamma \left( \frac{d-2+\eta}{2d} \right)}{\Gamma \left( \frac{3(d-2+\eta)}{2d} \right)} = 3.$$ \hspace{1cm} (A3)

When $d = 3$ and $\eta = 0.037$, one finds $\Gamma_4 = -0.987593$. As a comparison, the unrenormalized Ginzburg-Landau theory predicts $\Gamma_4 = -0.81156$. By contrast, numerical studies indicate $\Gamma_4 \simeq -1.4$. [3,20] While renormalization of the theory changes $\Gamma_4$ in the right direction,
the full scaling form is inadequate to the challenge of reproducing the correct value of this quantity.

The defect in the above analysis lies in the fact that finite size effects have been ignored. These effects are crucial at the critical point, where the bulk correlation length is infinite. As it turns out, the most important finite size effect is the prefactor. The influence of the prefactor is dramatically highlighted when one ignores the finite size contribution to Eq. (5.1) for $\ell^*$. If the coefficient $c$ is set equal to zero, the one finds immediately

$$e^{\ell^*} = \left(3uM^2\right)^{-1/(d-2+\eta)} . \tag{A4}$$

This means that the order parameter distribution is of the form

$$P(M) \propto M^{(2-\eta)/(d-2+\eta)} \exp\left[-\kappa M^{2d/(d-2+\eta)}\right] . \tag{A5}$$

The quantity $\kappa$ in the above equation is a combination of the size of the system, $L$, and the fourth order coupling constant, $u$. This quantity scales out of the result for $\Gamma_4$ in the same way that the constant $A$ divided out in the ratio in Eq. (A3). The result for $\Gamma_4$ following from Eq. (A5) is then

$$\Gamma_4 = \frac{\Gamma\left(\frac{2-\eta+5(d-2+\eta)}{2d}\right) \Gamma\left(\frac{2-\eta+(d-2+\eta)}{2d}\right)}{\Gamma\left(\frac{2-\eta+3(d-2+\eta)}{2d}\right)} - 3 . \tag{A6}$$

Inserting appropriate values for $d$ and $\eta$ into Eq. (A6), we obtain $\Gamma_4 = -1.69147$. In utilizing the prefactor as the sole finite size correction, we have overshot the proper value of $\Gamma_4$. Note, however, that the value obtained is independent of system size. Even though the prefactor is a finite size correction to the free energy, in the case of $\Gamma_4$ it is fully as important as the “leading order” contributions to the order parameter distribution.

As for the distribution $P(M)$, it is immediately evident that the prefactor leads to a depression in the neighborhood of $M = 0$. In fact, the order parameter distribution is forced to go to zero at $M = 0$ by the prefactor in Eq. (A5). This is a more pronounced effect than is desired. The suppression of the order parameter distribution is reduced when when finite size effects are restored to Eq. (5.1). It is the combination of these latter finite size
effects and the finite size correction embodied in the prefactor that yields a proper order parameter distribution at the critical point and a value of $\Gamma_4$ that is in agreement with previous determinations of this quantity.
FIG. 1. The order parameter distribution in the disordered phase, as obtained by Tsypin [1] (data points) and the results of the best constrained fit based on the effective Hamiltonian embodied in Eqs. (3.2) and (5.1).
FIG. 2. The order parameter distribution in the ordered phase, as obtained by Tsypin[1] (data points) and the results of the best constrained fit based on the effective Hamiltonian embodied in Eqs. (3.2) and (5.1).
FIG. 3. The order parameter distribution of the system at $t = 0$, as obtained by Tsypin[3] and the results of the fit using Eqs. (3.2) and (5.1). We include both the $16^3$ and $32^3$ systems on the plot.
