ABSTRACT

Angular momentum transport due to hydrodynamic turbulent convection is studied using local three-dimensional numerical simulations employing the shearing box approximation. We determine the turbulent viscosity from non-rotating runs over a range of values of the shear parameter and use a simple analytical model in order to extract the non-diffusive contribution (Λ-effect) to the stress in runs where rotation is included. Our results suggest that the turbulent viscosity is on the order of the mixing length estimate and weakly affected by rotation. The Λ-effect is non-zero and a factor of 2–4 smaller than the turbulent viscosity in the slow rotation regime. We demonstrate that for Keplerian shear, the angular momentum transport can change sign and be outward when the rotation period is greater than the turnover time, i.e., when the Coriolis number is below unity. This result seems to be relatively independent of the value of the Rayleigh number.

Key words: accretion, accretion disks – convection – stars: rotation – Sun: rotation – turbulence

Online-only material: color figures

1. INTRODUCTION

Turbulence due to the convective instability is thought to account for much of the angular momentum transport in the outer layers of the Sun and other stars with convection zones (e.g., Rüdiger 1989; Rüdiger & Hollerbach 2004, p. 47). In the presence of turbulence, the fluid mixes efficiently and diffusion processes occur much faster than in its absence. This effect is usually parameterized by a turbulent viscosity $\nu_t$ that is much larger than the molecular viscosity $\nu$. Often the value of $\nu_t$ is estimated using simple mixing length arguments with $\nu_t = \nu_{rm} l/3$, where $\nu_{rm}$ is the rms velocity of the turbulence and $l = \alpha_{MLT} H$ where $\alpha_{MLT}$ is a parameter of the order unity and $H$ is the vertical pressure scale height. Numerical results from simpler fully periodic isotropically forced systems suggest that the mixing length estimate gives the correct order of magnitude of turbulent viscosity (e.g., Yousef et al. 2003; Käpylä et al. 2009b; Snellman et al. 2009). However, it is important to compute $\nu_t$ from convection simulations in order to see whether the results of the simpler systems carry over to convection. Furthermore, it is of interest to study whether the small-scale turbulent transport can be understood in the light of simple analytical closure models that can be used in sub-grid-scale modeling. Measuring $\nu_t$ and its relation to averaged quantities, such as correlations of turbulent velocities, is one of the main purposes of our study.

In addition to enhanced viscosity, turbulence can also lead to non-diffusive transport. The $\alpha$-effect (e.g., Krause & Rädler 1980), responsible for the generation of large-scale magnetic fields by helical turbulence, is one of the most well-known non-diffusive effects of turbulence. An analogous effect exists in the hydrodynamical regime and is known as the Λ-effect (Krause & Rüdiger 1974). The Λ-effect is proportional to the local angular velocity and occurs if the turbulence is anisotropic in the plane perpendicular to the rotation vector (Rüdiger 1989).

The existence of the Λ-effect has been established numerically from convection simulations (e.g., Pulkkinen et al. 1993; Chan 2001; Käpylä et al. 2004; Rüdiger et al. 2005) and simpler homogeneous systems (Käpylä & Brandenburg 2008).

If, however, both shear and rotation are present, it is difficult to disentangle the diffusive and non-diffusive contributions. This is particularly important in the case of accretion disks where the sign of the stress determines whether angular momentum is transported inward or outward. Convection is commonly not considered as a viable angular momentum transport mechanism in accretion disks since several studies have indicated that the transport owing to convection occurs inward (e.g., Cabot & Pollack 1992; Ryu & Goodman 1992; Stone & Balbus 1996; Cabot 1996; Rüdiger et al. 2002). Furthermore, in an influential paper, Stone & Balbus (1996, hereafter SB96) presented numerical simulations of hydrodynamic convection where the transport was indeed found to be small and directed inward on average. This result was used to provide additional evidence for the importance of the magnetorotational instability (Balbus & Hawley 1991) as the main mechanism providing angular momentum transport in accretion disks. Although we agree with the conclusion that hydrodynamic turbulence is ineffective in providing angular momentum transport, we are concerned about the generality of the result of SB96. There are now some indications that hydrodynamic turbulence may not always transport angular momentum inward (cf. Lesur & Ogilvie 2010).

In order to approach the problem from a more general perspective, Snellman et al. (2009) studied isotropically forced turbulence under the influence of shear and rotation and found that the total stress, corresponding to the radial angular momentum transport in an accretion disk, can change sign as rotation and shear of the system are varied in such a way that their ratio remains constant. They found that the stress is positive for small Coriolis numbers, corresponding to slow rotation. In what follows, we show that outward transport is also possible for convection in a certain range of Coriolis numbers. When rotation is slow, the Reynolds stress is positive, corresponding to outward transport. In the regime of large Coriolis numbers, the Reynolds
stress changes sign and is directed inward, as in the study of SB96.

The remainder of the paper is organized as follows. Our numerical model is described in Section 2 and the relevant mean-field description in Section 3. The results and the conclusions are given in Sections 4 and 5, respectively.

2. MODEL

Our model is the same as that used in Käpylä et al. (2008), but without magnetic fields. We solve the following set of equations for compressible hydrodynamics,

$$\frac{D \ln \rho}{Dt} = -\nabla \cdot U, \quad (1)$$

$$\frac{Du}{Dt} = -SU_{x} \hat{y} - \frac{1}{\rho} \nabla p + g - 2\Omega \times U + \frac{1}{\rho} \nabla \cdot 2\nu \mathbf{S}, \quad (2)$$

where $\frac{D}{Dt} = \frac{\partial}{\partial t} + (U + \mathbf{U}_0) \cdot \nabla$ is the total advective derivative, $\mathbf{U}_0 = (0, S_0, 0)$ is the imposed large-scale shear flow, $\nu$ is the kinematic viscosity, $K$ is the heat conductivity, $\rho$ is the density, $U$ is the velocity, $g$ is the gravitational acceleration, and $\Omega = \Omega_0 z$ is the rotation vector. The fluid obeys an ideal gas law $p = \rho e(\gamma - 1)$, where $p$ and $e$ are pressure and internal energy, respectively, and $\gamma = c_v/c_p = 5/3$ is the ratio of specific heats at constant pressure and volume, respectively. The specific internal energy per unit mass is related to the temperature via $e = c_v T$. The traceless rate-of-strain tensor $\mathbf{S}$ is given by

$$S_{ij} = \frac{1}{2}(U_{i,j} + U_{j,i}) - \frac{1}{4} \delta_{ij} \nabla \cdot U, \quad (4)$$

where commas denote partial differentiation.

We use a three layer, piecewise polytropic stratification with constant gravity $g = -g(z)$. The vertical variation of $g$ in the real accretion disks is neglected in our local model. The positions of the bottom of the box, bottom and top of the convectively unstable layer, and the top of the box, respectively, are given by $(z_1, z_2, z_3, z_4) = (-0.85, 0, 1, 1.15)d$, where $d$ is the depth of the convectively unstable layer. Initially the stratification is piecewise polytropic with polytropic indices $(m_1, m_2, m_3) = (3, 1, 1)$. The horizontal extent of the box is twice the vertical extent, i.e., $L_x/d = L_y/d = 2L_z/d = 4$. The thermal conductivity has a vertical profile that maintains a convectively unstable layer above a stable layer at the bottom of the domain. A prescribed temperature gradient at the base maintains a constant heat flux into the domain. The last term in Equation (3) describes an externally applied cooling with

$$Q = \frac{e - e_0}{\tau_{cool}(z)}, \quad (5)$$

where $e_0$ is the internal energy at $z_4$, and $\tau_{cool}(z)$ is a cooling time which is constant for $z > z_3$ and smoothly connects to the lower layer where $\tau_{cool} \to \infty$.

We use impenetrable stress-free boundary conditions at the top and bottom boundaries for the velocity

$$\frac{\partial U_x}{\partial z} = \frac{\partial U_y}{\partial z} = U_z = 0. \quad (6)$$

The temperature gradient at the bottom of the domain is given by

$$\frac{\partial T}{\partial z} = \frac{-g/c_v}{(m_1 + 1)(\gamma - 1)}, \quad (7)$$

where $m_1 = 3$ is the polytropic index at $z_1$. All quantities are periodic in the $\gamma$-direction, whereas shearing periodic conditions (Wisdom & Tremaine 1988) are used in the $x$-direction. The same setup has been used in earlier work to model convection in local patches in a star, but here we also apply it to a layer near the surface of an accretion disk. The source of heating in the midplane of the disk is not specified and is instead assumed given. This is appropriate for addressing the more general question about the direction of angular momentum transport once there is convection in the absence of a magnetic field.

We employ the PENCIL CODE, which is a high-order finite difference code for solving the compressible MHD equations. The bulk of our simulations were performed at a moderate resolution of $128^3$ grid points. In a few cases, we study the behavior of the solutions at higher resolutions (up to $1024^3$; see Figure 1 for a snapshot of a high resolution simulation) showing the vertical velocity on the periphery of the domain.

2.1. Dimensionless Quantities and Parameters

Non-dimensional quantities are derived such that

$$d = g = \rho_0 = c_p = 1, \quad (8)$$

where $\rho_0$ is the initial density at $z_2$. The units of length, time, velocity, density, and entropy are

$$[x] = d, \quad [t] = \sqrt{d/g}, \quad [U] = \sqrt{d/g}, \quad [\rho] = \rho_0, \quad [s] = c_p. \quad (9)$$

The system is characterized by several non-dimensional parameters. We define the Prandtl number and the Rayleigh number as

$$Pr = \frac{\nu}{\chi_0}, \quad Ra = \frac{gd^4}{\nu \chi_0} \left(\frac{1}{c_p} \frac{ds}{dz}\right)_0, \quad (10)$$

where $\chi_0 = K/(\rho_m c_p)$ is a reference value for the thermal diffusivity, and $\rho_m$ is the density at the mid layer $z_m = \frac{1}{2}(z_3 - z_2)$. The entropy gradient, measured at $z_m$ in the non-convecting hydrostatic state, is given by

$$\left(\frac{1}{c_p} \frac{ds}{dz}\right)_0 = \frac{\nabla - \nabla_{ad}}{H_p}, \quad (11)$$

where $\nabla - \nabla_{ad}$ is the superadiabatic temperature gradient with $\nabla_{ad} = 1 - 1/\gamma, \nabla = (\partial \ln T/\partial \ln \rho)_n$, and $H_p$ is the pressure scale height at $z_m$. The amount of stratification is determined by the parameter $\xi_0 = (\gamma - 1)e_0/(gd)$, which is the pressure scale height at the top of the domain normalized by the depth of the unstable layer. We use in all cases $\xi_0 = \frac{1}{3}$, which results in a total density contrast of about 23. The Mach number in our simulations is of the order of 0.1 or less.

We define the Coriolis and shear numbers, describing the strengths of rotation and shear, respectively, as

$$Co = \frac{2\Omega_0}{u_{rms} k_f}, \quad Sh = \frac{S}{u_{rms} k_f}. \quad (12)$$

http://pencil-code.googlecode.com/
where $u_{\text{rms}}$ is the rms value of the turbulent velocity averaged over the full volume, $k_f = 2\pi/d$ is an estimate of the energy carrying wavenumber, and $d$ is the depth of the convectively unstable layer. The Reynolds number is given by

$$\text{Re} = \frac{u_{\text{rms}}}{\nu k_f}. \quad (13)$$

For accretion disk applications it is convenient to define also the relative shear rate,

$$q = -\frac{S}{\Omega_0}, \quad (14)$$

which describes the rotation profile of the disk, where the local angular velocity varies like $\Omega \propto r^{-q}$. For Keplerian disks we have $q = 3/2$.

The majority of the simulations ran for $10^3$ time units ($\Delta t = 10^3 \sqrt{d/g}$), which corresponds to roughly 250 convective turnover times; $t_{\text{run}} = (u_{\text{rms}} k_f)^{-1}$. For the analysis the first 50 turnover times of the simulations were usually discarded in order to minimize the effects of initial transients. The highest resolution runs with $512^3$ and $1024^3$ grid points were started by remeshing from snapshots of lower resolution runs and ran for 60 and 14 turnover times, respectively.

Error bars are estimated by dividing the time series into three equally long parts and computing averages for each part individually. The largest departure from the average over the full time series is taken to represent the error.

### 3. MEAN-FIELD INTERPRETATION

In mean-field hydrodynamics, the velocity field is decomposed into its mean and fluctuating parts,

$$U = \overline{U} + u, \quad (15)$$

where the overbar denotes averaging and lowercase $u$ the fluctuation. In the present paper, we consider horizontal averaging so that the mean quantities depend only on $z$. We define the Reynolds stress as

$$R_{ij} = \overline{u_i u_j}. \quad (16)$$

Fluctuations of the density are here ignored for simplicity.

The Reynolds stress is often described in terms of the Boussinesq ansatz which relates the stress to the symmetrized gradient matrix of the large-scale velocity

$$R_{ij} = -N_{ijkl} \overline{U_k l} + \ldots, \quad (17)$$

where the dots indicate higher derivatives of $\overline{U}$ that can occur in the expansion. The expression (17) states that the stress is diffusive in character. In the general case, the fourth rank tensor $N_{ijkl}$ can have a complicated structure (see, e.g., Rüdiger 1989). However, if we assume that the shear is weak, the simplest description of the horizontal stress generated by our linear shear flow is given by

$$R_{xy} = -\nu_t S_{xy} = -\nu_t S, \quad (18)$$

where $\nu_t = \nu_t(z)$ is the $z$-dependent turbulent viscosity, and the component $S_{xy}$ of the rate-of-strain tensor is not to be confused with the shear rate $S$. To our knowledge, SB96 present the only published results of turbulent viscosity in the absence of rotation as determined from convection simulations with large-scale shear, and they only provide a volume averaged quantity for one case. If also rotation is present (cf. Cabot 1996; Lesur & Ogilvie 2010) the Reynolds stress can no longer be related to turbulent viscosity alone (see below). In the present paper, we study the dependence between stress and shear systematically and estimate the turbulent viscosity coefficient $\nu_t$.

It turns out that in many applications, Equation (17) is insufficient to describe the stress. For example, according to Equation (18), the Reynolds stress component $R_{\theta \phi}$ derived from observations of sunspot proper motions with the observed surface differential rotation would yield $\nu_t < 0$, which is clearly
unphysical (see the discussions in Tuominen & Rüdiger 1989; and Pulkkinen et al. 1993). This motivates the inclusion of a non-diffusive contribution proportional to the rotation of the system (e.g., Wasiutynski 1946), such that

\[ R_{ij} = \Lambda_{ijk} \Omega_k - N_{ijk} \bar{U}_{k,1} + \ldots, \]  

(19)

where \( \Lambda_{ijk} \) are the components of the \( \Lambda \)-effect. This effect is expected to occur in anisotropic turbulence under the influence of rotation (e.g., Rüdiger 1989). In convection the density stratification provides the anisotropy. This is confirmed by numerous simulations of rigidly rotating stratified convection (e.g., Pulkkinen et al. 1993; Chan 2001; Käpylä et al. 2004; Rüdiger et al. 2005). Although additional shear flows are generated in these systems when the gravity and rotation vectors are not parallel or antiparallel, no serious attempt has been made to quantify the turbulent viscosity in convection.

When shear and rotation are both present, it is no longer possible to distinguish between the diffusive and non-diffusive contributions without resorting to additional theoretical arguments. Here, we use a simple analytical approach based on the so-called minimal \( \tau \)-approximation (see, e.g., Blackman & Field 2002, 2003) to estimate the contributions from \( \nu_t \) and the \( \Lambda \)-effect.

The idea behind the minimal \( \tau \)-approximation is to use relaxation terms of the form \( -\tau^{-1} R_{ij} \) in the evolution equations for the components of the Reynolds stress \( R_{ij} \) as a simple description of the nonlinearities. Using the decomposition (Equation (15)) and the Navier–Stokes equations one can derive equations for the Reynolds stress. For the purposes of the present study it suffices to consider a situation with one spatial dimension, \( z \). In this case, the evolution equations can be written

\[ \tau \nu_t = -R_{xy}^{(S)}/S, \]  

(22)
is equal to unity, i.e., $\tau = \tau_{\text{turn}}$, we obtain

$$v_{10} = \frac{1}{3} u_{10}k_{f}^{-1}. \quad (25)$$

Note that if we allow $St \neq 1$, we have $v_{10} = \frac{1}{3} S u_{10} k_{f}^{-1}$, and the ratio $v_{1}/v_{10}$ gives a measure of the Strouhal number. A typical example of $v_{1}$ is shown in Figure 2. We find that the stress owing to the large-scale shear is always positive, yielding $v_{1} > 0$. The stress $R_{xy}$ increases roughly proportionally to the shear parameter $S$ in the range $0.04 < [Sh] < 0.17$ so that the ratio $v_{1}/v_{10}$ remains approximately constant; see Figure 3. Increasing the shear much beyond our relatively low maximum value leads to large-scale vorticity generation. These flows often grow so strong that the Mach number reaches unity, leading to numerical difficulties. We associate this phenomenon with the “vorticity dynamo” observed in forced turbulence simulations (Yousef et al. 2008; Käpylä et al. 2009b) and several theoretical studies (e.g., Elperin et al. 2003, 2007). Although the large-scale vorticity generation is weak in our runs A1–A4, we see that in the absence of rotation even modest shear increases the rms velocity measurably (see Table 1). However, when rotation is added, this instability vanishes (see, e.g., Snellman et al. 2009).

Our estimate for $v_{10}$ is based on the volume averaged rms velocity and a somewhat arbitrarily defined length scale $1/k_{f}$.
Figure 5. Same as Figure 4, but for a subset of runs from set C with positive values of \( q \) (see the legend).

\[ -0.5 \]

\[ 0.5 \]

\[ 1.0 \]

\[ 0.0 \]

\[ 0.2 \]

\[ 0.4 \]

\[ 0.6 \]

\[ \text{Co}=0.00 \text{ (Run A4)} \]

\[ \text{Co}=0.20 \text{ (Run C1)} \]

\[ \text{Co}=0.30 \text{ (Run C3)} \]

\[ \text{Co}=0.49 \text{ (Run C6)} \]

\[ \text{Co}=1.02 \text{ (Run C8)} \]

\[ \text{Co}=2.19 \text{ (Run C7)} \]

\[ \text{Co}=7.46 \text{ (Run C8)} \]

\[ \text{Sh} \sim -0.22 \]

\[ \text{Co} \gtrsim -0.04 \], the differences between the runs are not statistically significant (cf. Figure 2 and Table 1). This is also clear from Figure 6, where we plot the volume average of the stress over the convectively unstable layer as a function of rotation. For more rapid rotation, we interpret the decrease of the stress as the non-diffusive contribution due to the \( \Lambda \)-effect which is likely a good approximation for slow rotation (see below). The situation is less clear in the case of positive \( q \); see Figure 5 and the inset of Figure 6. A contributing factor is that we cannot use arbitrarily small \( \Lambda \) in the positive \( q \) regime because cases with \( q > 2 \) are Rayleigh unstable. However, in the runs that can be done the stress is somewhat decreased in comparison to runs with corresponding [Co] and negative \( q \). For the most rapidly rotating cases in set C the sign of the stress changes, which is not observed in set B. The sign change suggests that the \( \Lambda \)-effect dominates over the turbulent viscosity in the rapid rotation regime. Similar asymmetry between the regimes of positive and negative \( q \) have also been reported, e.g., by Snellman et al. (2009) and Korpi et al. (2010).

It is interesting to see whether simple analytical models can reproduce the simulation results. For example, in the presence of weak shear and rotation, the minimal \( \tau \)-approximation applied to a homogeneous system with no convection gives (see Appendix A.2 of Snellman et al. 2009)

\[
\langle R_{xy} \rangle = a_1 \text{St} \frac{(Co + Sh)(R_{xx}^{(0)} + Co \langle R_{yy}^{(0)} \rangle)}{1 + 4 Co \text{St}^2(Co + Sh)},
\]

(29)

where angular brackets denote volume averaging and the superscript 0 refers to a non-rotating and non-shearing reference state. A similar result was obtained earlier for arbitrary shear and rotation by Narayan et al. (1994) with a conceptually different model where individual eddies were treated as particles that scatter off each other. We note that neither of these models is directly applicable to the present system, although treatment of convection can be introduced into the models (e.g., Kumar et al. 1995). However, our purpose here is not to perform a detailed comparison of the closure models with simulations but rather to attain a broad understanding of the system. In Figure 6, we compare the numerical results with the analytical estimate given in Equation (29), keeping the Strouhal number as a free parameter. Furthermore, we have introduced a scaling parameter \( a_1 (=1.7) \) in order to improve the fit.

We find that parameters St = 1.0 and \( a_1 = 1.7 \) produce a good fit to the numerical results for the runs in set B. We have here normalized our results from Equation (29) by the value of \( u_{rms} \) from the non-rotating run A0, so a scaling factor \( a_1 \) greater than unity can in principle be understood to reflect the decrease of \( u_{rms} \) as rotation is increased. However, this scaling is not essential since even the unscaled curve shows qualitatively the same behavior. The fit for the runs in set C is not as successful although the simple model coincides with the simulation data for intermediate values of Co. However, the simulation results fall below the model for \( q > 1.25 \) and the negative stresses for rapid rotation are not captured by the model. The latter is in line with the discovery of Snellman et al. (2009) that the validity of the minimal \( \tau \)-approximation is limited to the slow rotation regime. The lack of proper parameterization of thermal convection in our simple model is another obvious reason for the differences.

4.3. \( \Lambda \)-effect Due to Shear-induced Anisotropy

In the absence of shear, but including rotation parallel or antiparallel to gravity, turbulence is statistically axisymmetric and there is no asymmetry between the turbulence intensities in the two horizontal directions, i.e., \( R_{xx} = R_{yy} \). This implies that there is no horizontal \( \Lambda \)-effect which, to the lowest order, is proportional to (Rüdiger 1989)

\[
R_{xy}^{(4)} = \Lambda_1 \Omega_0 = 2 \Omega_0 \tau (R_{yy} - R_{xx})
\]

(30)

Note that the same result is borne out of Equation (20) if we assume that all large-scale flows vanish and allow deviations from axisymmetry, i.e., \( R_{xx} \neq R_{yy} \). However, when shear is included, the turbulence becomes anisotropic in the horizontal plane, enabling the generation of a non-diffusive contribution to the stress \( R_{xy} \) due to rotation, according to Equation (30). Such contributions have earlier been studied analytically (Leprovost & Kim 2007, 2008a, 2008b) and numerically (Snellman et al. 2009) for isotropically forced homogeneous turbulence.

When both shear and rotation are present it is not possible to separate the diffusive from the non-diffusive contribution directly. Furthermore, using the diffusive stress from a purely shearing run to extract the non-diffusive one from a run with both the effects is also problematic due to the relatively large errors in the data (cf. Figure 6) which can lead to spurious results. The large errors in the purely shearing runs can possibly...
be explained by a subcritical vorticity dynamo (cf. Section 4.1). However, if rotation is slow, we can use the simple analytical results of Equations (28) and (30) to express the total stress as

\[ R_{xy} = 2\Omega t (R_{yy} - R_{xx}) - \tau R_{xx} S. \]  

(31)

On the other hand, we can express the stress in terms of the \( \Lambda \)-effect and turbulent viscosity by

\[ R_{xy} = \Lambda t \Omega - \nu t S, \]  

(32)

where we now have

\[ \Lambda t = 2\tau (R_{yy} - R_{xx}), \quad \nu t = \tau R_{xx}, \]  

(33)

and where we again treat \( \tau \) as a fitting parameter. Figure 7 shows an example from run B5. We find that, when \( \tau \) corresponding to \( St \approx 2 \) is used, the total stress is in broad agreement with Equation (31). In addition to the weaker negative diffusive contribution, corresponding to the turbulent viscosity, we find a non-diffusive part of the opposite sign. Reasonably good fits can be obtained for runs with \( |Co| < 1 \) with a \( \tau \) corresponding to \( St \approx 2 \). For more rapidly rotating cases the representation Equation (31) breaks down. Furthermore, in the rapid rotation regime the relevant time scale is the rotation period rather than the turnover time. For the purposes of visualization, and without altering the qualitative character of the results, we consider here volume averages over the convectively unstable layer. Results for runs B1–B7 are shown in Figure 8. We use a fixed \( \tau = 8\sqrt{\bar{d}/g} \), which corresponds to \( St \approx 1.5–2.1 \) in these runs. We find that the total stress is fairly well reproduced for runs where \( |Co| \) is below unity. Furthermore, the diffusive contribution stays almost constant as a function of \( Co \), whereas the non-diffusive part is close to zero for \( |Co| < 0.1 \). The turbulent viscosity, as obtained from Equation (33), shows a weak declining trend as a function of rotation, see the lower panel of Figure 8. The coefficient \( \Lambda t \) has values in the range \((0.5–1)\nu t_0\) for slow rotation. The error estimates increase toward slow rotation, which is consistent with the fact that the non-diffusive stress is small at low Coriolis numbers. These results suggest that the \( \Lambda \)-effect is non-zero when the anisotropy of the turbulence is induced by the shear flow with a roughly rotation-independent coefficient \( \Lambda t \). However, as our method breaks down when \( |Co| \geq 1 \), we cannot study quenching behavior of \( \nu t \) and the \( \Lambda \)-effect for rapid rotation.

4.4. Dependence on Reynolds Number

In set D, we vary the Reynolds number, keeping shear and rotation fixed. Here, we choose \( q = 1.5 \), corresponding to Keplerian shear. Again, the values of \( Co \) and \( Sh \) are not exactly constant due to the varying \( u_{rms} \); see Table 2. Figure 9 shows the results for the horizontally averaged stress from the runs in set D. We find that for relatively weak shear and rotation, the stress is positive in the convectively unstable layer—in apparent contradiction with some earlier results (Stone & Balbus 1996; Cabot 1996) but in accordance with the recent results of Lesur & Ogilvie (2010). We discuss this issue in the next section in detail.

We also find that the vertical distribution and magnitude of the stress are not much affected when the Reynolds number is increased from 28 to 648, see the inset of Figure 9, where \( R_{xy} \) averaged over the convectively unstable layer and time is shown. We note that in addition to the Reynolds number, the Rayleigh number in this set changes by a factor of 20. However, we have kept the heat conduction, \( K \), and thus the input energy flux, constant so that \( u_{rms} \) varies by only 10% within set D. Had we kept \( Pr = 1 \), the energy input at the lower boundary would have also decreased by a factor of 20. This would have resulted in a much lower \( u_{rms} \) and thus proportionally greater values of \( Co \) and \( Sh \). This would have likely produced a very different trend as a function of \( Ra \) because \( Co \) and \( Sh \) are considered as the relevant dimensionless parameters for the Reynolds stress (see, e.g., Snellman et al. 2009).
In a recent study, Lesur & Ogilvie (2010) presented results from Boussinesq convection in an otherwise similar shearing box setup as ours. They report that the stress changes sign from negative to positive in the Keplerian case for strong shear when the Rayleigh number is increased sufficiently. This appears to be in contradiction with our results regarding the dependence on Rayleigh number. However, in their setup the Richardson number (Ri), defined as the negative of the ratio of the squared Brunt–Väisälä frequency and the squared shear rate, is less than unity. This indicates that their models are in the shear-dominated regime whereas in our case only one simulation (run E8) falls in this regime. The low-Ri case at high Rayleigh numbers certainly merits further study.

4.5. Relation to Accretion Disk Theory

In their paper, Stone & Balbus (1996) performed a numerical simulation of convection in a local accretion disk model and found that the total stress is small and on average directed inward. This numerical result based on one simulation and insight drawn from analytical arguments led them to conclude that convection cannot account for the outward angular momentum transport required in astrophysical accretion disks. However, numerical simulations of isotropically forced homogeneous turbulence under the influence of shear and rotation indicate that the total stress can change sign as a function of Co when q is fixed (Snellman et al. 2009). In their study, Snellman et al. (2009) found that, for slow rotation, the stress is positive and changes sign near Co = 1. For rapid rotation (Co ≈ 10) the stress appears to drop close to zero. In the context of mean-field hydrodynamics, this can be understood as quenching of the A-effect and turbulent viscosity due to shear and rotation, i.e., \( \Lambda_{\text{H}} = \Lambda_{\text{H}}(\Omega, S) \) and \( v_t = v_t(\Omega, S) \).

In an effort to study how these results carry over to convection, we perform a set of runs where we keep q = 1.5 fixed and vary the values of Co and Sh. Our results for the horizontally averaged stress are shown in Figure 10. For slow rotation and weak shear, \( R_{xy} \) is positive with a maximum value of roughly 10% of the mean square velocity. As we increase the rotation, the stress decreases and changes sign for Co ≈ 2. For Co = 4.33, \( R_{xy} \) is negative everywhere in the convectively unstable layer. This is when the flow pattern has become markedly anisotropic, as can be seen from visualizations of \( U_z \) on (or near) the periphery of the computational domain (Figure 11). Indeed, the flow pattern becomes rather narrow in the cross-stream direction, while being roughly unchanged in the streamwise direction. In the rapid rotation regime, the non-axisymmetric structures tend to disappear and promote a two-dimensional flow structure that leads to inward transport (Cabot 1996), which is also visible from our results.

Let us now ask under what conditions can we expect outward angular momentum transport in accretion disks; i.e., when can one expect the Coriolis number to be below unity? In disks, we have \( \Omega_d H = c_s \), where \( H \) is the scale height and \( c_s \) is the sound speed. Inserting this into our definition of Co we obtain from Equation (12)

\[
\text{Co} = \frac{2 \Omega_0}{u_{\text{rms}} k_l} = \frac{2 \Omega_0 H}{u_{\text{rms}} k_l H} = \frac{2}{k_l H} \frac{\alpha}{\pi} \Lambda_{\text{H}}^{-1},
\]

where we have defined the turbulent Mach number \( M_{\text{t}} = u_{\text{rms}} / c_s \). In our simulations, \( k_l H \) is of order unity, which would suggest that we can expect Co < 1 only for supersonic turbulence.

A more refined estimate can be obtained by invoking the Shakura–Sunyaev \( \alpha \)-parameter (Shakura & Sunyaev 1973), which is introduced as a parameterization of the turbulent viscosity \( \nu_t \) via

\[
\nu_t = \alpha c_s H.
\]

(35)

We can use this parameterization together with Equation (23) to eliminate \( u_{\text{rms}} \) in favor of \( \alpha \) under the assumption that \( v_t \approx v_{t0} \). This leads to

\[
\text{Co} = \frac{2 c_s}{3 \nu_t k_l H} = \frac{2}{3 \alpha (k_l H)^2}.
\]

(36)

In our simulations, we have \( H \approx 0.62d \) at the base of the convectively unstable layer. Together with our estimate \( k_l = 2 \pi / d \) this yields \( k_l H \approx 4 \), and therefore Co ≈ (24\( \alpha \))\(^{-1} \). We can therefore expect Co < 1 for accretion disks where the turbulence is sufficiently vigorous so that \( \alpha \gtrsim 0.04 \).

We now use our simulations to estimate \( \alpha \). In disks, the rate of strain is proportional to \( q \Omega_0 \), so the total turbulent stress is given by

\[
T_{xy} = v_t q \Omega_0,
\]

(37)

where, in the absence of any other stresses such as from magnetic fields, the total stress per unit mass is given by

\[
T_{xy} \equiv u_x u_y,
\]

(38)
Combining Equations (35) and (37) gives

$$\alpha = \frac{T_{xy}}{q\Omega_0 c_s H}. \quad (39)$$

We compute $T_{xy}$ and hence $\alpha$ as volume averages over the convectively unstable region. For the normalization factor, we take conservative estimates of $c_s$ and $H$ from the bottom of the convectively unstable layer. We find that for slow rotation, i.e., $Co < 0.2$, $\alpha$ is roughly constant with a value of the order of 0.01 (see Figure 12). For more rapid rotation $\alpha$ decreases and eventually changes sign. The points in the range $Co \approx 0.06–1$ are consistent with a scaling inversely proportional to the Coriolis number for reference. We find that for $Co \approx 1$ we have $\alpha \approx 4 \cdot 10^{-4}$ which is two orders of magnitude smaller than the estimate derived above.

Another problem facing the suggestion that convection might drive the angular momentum transport in accretion disks is that without an internal heat source in the disk, convection is not self-sustained (cf. SB96). However, many disks are likely to be susceptible to the magnetorotational instability which can extract energy from the shear flow and ultimately deposit it as thermal energy in the disk. If the material in the disk is sufficiently thick optically, the pileup of energy from the magnetorotational instability could render the vertical stratification of the disk convectively unstable.

As alluded to in the introduction, our aim is not to claim that convection is solely responsible for the outward angular momentum transport in accretion disks but to show that, given the right conditions, convection can contribute to outward angular momentum transport.

5. CONCLUSIONS

The present results have shown that hydrodynamic convection is able to transport angular momentum both inward and outward, depending essentially on the value of the Coriolis number, in accordance with earlier results from homogeneous isotropically forced turbulence (Snellman et al. 2009). This underlines the importance of considering comprehensive parameter surveys and not relying on demonstrative results from individual case studies. For given value of the Coriolis number, the stress is found to be relatively independent of the value of the Rayleigh number (Section 4.4). By varying shear and rotation rates separately, we have been able to quantify the relative importance of diffusive and non-diffusive contributions to the Reynolds stress tensor. In agreement with earlier work, it turns out that the turbulent kinematic viscosity is of the order of the mixing length estimate and has roughly the same value as the turbulent magnetic diffusivity found earlier for similar runs (Käpylä et al. 2009a). In other words, the turbulent magnetic Prandtl number is around unity, again in accordance with results from simpler systems (e.g., Yousef et al. 2003).

The other important turbulent transport mechanism in rotating turbulent bodies is the $\Lambda$-effect. Although the importance of...
this effect is well recognized in solar and stellar physics (e.g., Rüdiger & Hollerbach 2004), it is not normally considered in the context of accretion disks. In the present paper, we have been able to quantify its importance for a range of Coriolis numbers by means of a simple analytical model making use of the minimal \( \tau \)-approximation. For slow rotation the coefficient \( \Lambda_H \) is of the order of \( \nu t_0 \) and independent of the Coriolis number. However, once the Coriolis number exceeds a value around unity, our method of separating the turbulent viscosity and the \( \Lambda \)-effect breaks down, which reinforces the need for a truly independent determination not only of diffusive and non-diffusive contributions to the Reynolds stress, but also of all the components of the full stress tensor.
