I. INTRODUCTION

The growth of large scale structure in the universe is a multifaceted probe of cosmology. The galaxy clustering pattern measures cosmic geometry through baryon acoustic oscillations, giving angular distances transverse to the line of sight and radial distance intervals, or the Hubble parameter, along the line of sight, and the ratio of the two known as the Alcock-Paczyński effect [1]. The evolution of the clustering amplitude provides the growth factor and the shape of the clustering correlation function or power spectrum depends on early universe conditions and later, scale dependent effects. In addition, redshift space distortions (RSD) cause anisotropy in the clustering between the transverse and radial directions, and this probes the velocity field and the law of gravity [2–7].

General relativity (GR) predicts scale independent growth in the linear perturbation regime and specific redshift distortion patterns, and so probing for scale dependence or distortion deviations can test the theory of gravity. Our aim is to investigate the general relativity cosmological framework by fitting the galaxy clustering data while allowing for scale dependence, and constrain such deviations. We are particularly motivated by scalar-tensor theories and use a perturbation theory template derived for $f(R)$ gravity. Scale dependence arises at length scales smaller than or of order the inverse of the scalaron mass $m = 1/\sqrt{3f_{RR}}$, where a subscript $R$ denotes a derivative with respect to the Ricci scalar [8]. For GR, $f = R$ and so the scale dependence vanishes. This scale dependence was tested using the combination of cosmic microwave background (CMB) data and galaxy clustering spectra in the following work [9].

By employing the perturbation theory of Taruya et al. [10] that uses a resummed propagator to partially include nonperturbative and screening effects of the modified gravity, we can analyze the clustering correlation function to smaller scales than linear theory or simple perturbation calculations. We join this to our previous, substantially model independent approach of treating the background expansion in terms of the angular diameter distance and Hubble parameter [11–13], rather than assuming a dark energy model such as $\Lambda$CDM. Furthermore, we generalize the previous scale independent growth factor to two quantities: one scale independent (corresponding to the large scale limit of the growth factor) and one scale dependent (which can be thought of as characterizing the scalar-tensor modification, e.g. $m$ or $f_{R0}$).

While we concentrate here on improving the RSD and galaxy clustering analysis for testing GR, various other methods have also been used. For example, the Planck collaboration has put constraints on a wide range of modified gravity models using the Planck 2015 CMB data. We generalize the previous scale independent growth factor to two quantities: one scale independent (corresponding to the large scale limit of the growth factor) and one scale dependent (which can be thought of as characterizing the scalar-tensor modification, e.g. $m$ or $f_{R0}$).
data, combined with large scale structure observations [14]; the SDSS-III (BOSS) team has tested GR using the observed structure growth patterns [15–17]; the Wiggle-z team has tested modified gravity models [18, 19]; and the CFHTLenS team employs the complementarity between weak gravitational lensing and RSD [20]. The abundance of clusters [21, 22] and the cluster profiles [23, 24] have also been used for gravity tests. For more recent observational tests of GR, see [25–32] and [33] for a review.

To focus on exploring the scale dependence, we use only the clustering data, from the Baryon Oscillation Spectroscopic Survey (BOSS) Data Release 11 (DR11) of the Sloan Digital Sky Survey 3 (SDSS3) [34, 35]. This consists of about 690,000 galaxies over an effective volume of 6 Gpc$^3$ with an effective redshift $z = 0.57$. We measure the two dimensional anisotropic correlation function as a function of transverse and radial separation between galaxies, and fit this to the redshift space distorted resummed perturbation theory. This comparison then imposes constraints on the cosmological and gravitational quantities, allowing us to test general relativity.

Section II describes the modified gravity theoretical approach, from the $f(R)$ gravity model to the resummed propagator and resulting perturbation theory to the prediction for the clustering correlation function. We also lay out our approach of splitting the growth function into scale independent and dependent parts. In Sec. III A we discuss measurement of the anisotropic correlation function from the data and treatment of the covariance matrix. We verify in Sec. III B that we recover ΛCDM from ΛCDM simulated data. The comparison of the theory to the measurement is in Sec. III C and III D, where we analyze the fits to the cosmological quantities and their consistency with general relativity and ΛCDM. We summarize and conclude in Sec. IV.

II. THEORETICAL MODEL

A. $f(R)$ gravity model

We consider perturbations around the Friedman-Robertson-Walker universe described by the metric

$$ds^2 = -(1 + 2\Psi)dt^2 + a(t)^2(1 - 2\Phi)\delta_{ij}dx^idx^j.$$  

We will investigate modified gravity models that can be modelled by Brans-Dicke gravity on subhorizon scales. The metric perturbations and the scalar field perturbation $\phi = \phi_0 + \phi$ obey the following equations in Fourier space [36]

$$-\frac{k^2}{a^2}\Psi = 4\piGa^2\rho\delta + \frac{1}{2}k^2\phi,$$  

$$(3 + 2\omega_B)\frac{1}{a^2}k^2\phi = 8\piG\rho_m\delta - I(\phi),$$  

$$\Phi - \Psi = \phi,$$

where $I$ represents the self-interaction, which can be expanded as [36]

$$I(\phi) = M_1(k)\phi(k) + \frac{1}{2}\int \frac{d^3k_1d^3k_2}{(2\pi)^6}\delta_D(k - k_{12})M_2(k_1, k_2)\phi(k_1)\phi(k_2)$$

$$+ \frac{1}{6}\int \frac{d^3k_1d^3k_2d^3k_3}{(2\pi)^6}\delta_D(k - k_{123})M_3(k_1, k_2, k_3)\phi(k_1)\phi(k_2)\phi(k_3),$$

where $k_{ij} = k_i + k_j$ and $k_{ijk} = k_i + k_j + k_k$. We treat the matter fluctuations $\delta$ as a pressureless fluid flow, whose evolution equation is given by

$$\frac{\partial\delta}{\partial t} + \frac{1}{a}\nabla \cdot [(1 + \delta)\mathbf{v}] = 0, \quad (6)$$

$$\frac{\partial\mathbf{v}}{\partial t} + H\mathbf{v} + \frac{1}{a}(\mathbf{v} \cdot \nabla)\cdot \mathbf{v} = -\frac{1}{a}\nabla\Psi. \quad (7)$$

We will assume the irrotationality of fluid quantities and express the velocity field in terms of the velocity divergence $\Theta = \nabla \cdot \mathbf{v} / (aH)$.

In order to develop the template for the redshift space power spectrum, we need to specify the interaction term $I$. We consider $f(R)$ models as a representative class of models where the linear growth function is scale depen-
where $f_R = df/dR$ and the bar indicates that the quantity is evaluated on the background. $f(R)$ gravity models are equivalent to Brans-Dicke gravity with $\omega_{BD} = 0$ and the interaction term $\mathcal{I}$ is given by

$$\mathcal{I} = \delta R \equiv R(f_R) - R(\bar{f}_R).$$

Thus the coupling functions $M_n$ are

$$M_n = \frac{d^n\bar{R}(f_R)}{df_R^n},$$

so Eq. (9) gives

$$M_1 = \frac{1}{2} \frac{\bar{R}^3}{|f_{R0}| R_0^2}.$$  \hspace{1cm} (13)

By linearising the evolution equations, the solution for the gravitation potential is given by

$$k^2 \Psi = -4\pi G \left( \frac{4 + M_1 a^2/k^2}{3 + M_1 a^2/k^2} \right) a^2 \rho_m \delta,$$  \hspace{1cm} (14)

On scales larger than the Compton wavelength of the scalar field, $m^{-1} = (3/M_1)^{1/2} = \sqrt{3\bar{f}_R}$, the scalar field does not propagate and we recover $\Lambda$CDM. On the other hand, on small scales, gravity is enhanced: $G_{\text{eff}} \to (4/3)G$.

Combining this with the energy momentum conservation equations, we obtain the equation that determines the linear growth factor $D^\delta_+(k,t)$,

$$\mathcal{L} D^\delta_+ = 0, \quad \mathcal{L} = \frac{d^2}{dt^2} + 2H \frac{d}{dt} - 4\pi G \left( \frac{4 + M_1 a^2/k^2}{3 + M_1 a^2/k^2} \right) \rho_m.$$  \hspace{1cm} (15)

The growth function $D^\delta_+$ and the growth rate $D^\delta_+/d\log a$ are also scale dependent. We introduce the following parametrisation of the growth rates

$$D^\delta_+(k,t) = G_\delta(t) F_\delta(k,t;M_1),$$

$$D^\delta_+(k,t) = G_\Theta(t) F_\Theta(k,t;M_1),$$  \hspace{1cm} (16)

where we defined $F_\delta(k,t;M_1)$ and $F_\Theta(k,t;M_1)$ so that $D^\delta_+(k,t) \to G_\delta(t)$ and $D^\delta_+(k,t) \to G_\Theta(t)$ in the limit of $k \to 0$. Since we recover $\Lambda$CDM in the $k \to 0$ limit, $G_\delta$ and $G_\Theta$ are determined by the usual cosmological parameters and they are independent of $|f_{R0}|$. On the other hand, the scale dependence is controlled by $M_1$ in Eq. (14), which is determined by $|f_{R0}|$ and the cosmological parameters.

We will find solutions for $\delta$ and $\Theta$ by solving Eqs. (2), (3), (6), (7) using perturbation theory. Once the non-linearity becomes important, the non-linear self-interactions $M_{i>1}$ will suppress the scalar field interactions by the chameleon mechanism. This effect is included perturbatively in our approach.
The anisotropy of galaxy clustering is now recognized as a useful probe of gravity on cosmological scales. This is because the anisotropic clustering signal contains information on both the cosmic expansion and growth of structure, through the Alcock-Paczynski effect and RSD. In principle, these two effects are simply described by the mapping formula from the statistically isotropic frame, however modeling the RSD effect is rather complex because of the nonlinear and stochastic nature of the mapping. As a result, the applicable range of the linear theory prediction is quite limited. Even at the largest scales accessible by future galaxy surveys, a proper account of corrections up to the one-loop order in the UV behaviour, we shall apply the resummed perturbation theory called RegPT, which has been formulated in Ref. [43] and been later extended in Ref. [10] to the modified gravity models. Following the prescription described in [10], we compute the power spectra $P_X(k)$ as well as the $A$ and $B$ terms, including consistently the nonlinear corrections up to the one-loop order in the $f(R)$ gravity model. The explicit expressions for statistical quantities, necessary for a consistent one-loop calculation of the redshift-space power spectrum, are summarized in Appendix A.

In the cosmological analysis in Sec. III, we will consider the following two cases, which can be thought of as fixing the expansion and large scale growth histories, or allowing them to vary. In the first case, we will fix all the cosmological parameters in the template by a fiducial cosmology and vary $|f_{R0}|$, the linear bias $b$ and the velocity dispersion $\sigma_p$. This corresponds to fixing $G_\delta$, $\rho_0$ and the amplitude of the initial spectrum to those determined by the fiducial cosmology.

In the second case, we allow $G_\delta$ to float by varying $\Omega_\Lambda \equiv \rho_\Lambda/3H_0^2$ where $H_0$ is the present day Hubble constant in the flat universe. Note that with the variation of $\Omega_\Lambda$, the amplitude of the growth function $D_{\Omega}(G_\delta)$ as well as the shape of the growth function $(F_3)$ and growth rate $(F_\delta)$ are also changed through the mass parameter $M_1$ [see Eq. (15)]. In practice, however, we see from Fig. 1 that the dependence of the shapes $F_3$ and $F_\delta$ on $\Omega_\Lambda$ are very weak. Further, the change of $G_\delta$ is degenerate with the linear bias $b$ in the linear regime. Although

\[ A = b^3 \sum_{n=1}^{3} \sum_{a,b=1}^{2} \mu^{2n} \left( \frac{G_\delta}{b} \right)^{a+b-1} \int_{-1}^{1} dr \int_{-1}^{1} dx \times \left\{ A_{ab}^n(r, x) B_{2ab}(p, k - p, -k) + \tilde{A}_{ab}^n(r, x) B_{2ab}(k - p, p, -k) \right\} \]
the one-loop terms break the degeneracy, this effect is small in the regime of our interest. Hence, in the second case, we vary the scale independent growth rate $G_b$ and the linear bias in the PT template, and introduce a new parameter

$$G_b(t) \equiv b G_\delta(t),$$

(21)

to represent the combined effect of the variation of $b$ and $G_\delta$. Then $G_\delta$ and the initial amplitude of the power spectrum are formally held fixed.

C. Correlation function $\xi(\sigma, \pi)$ in $f(R)$ gravity

The two-point correlation function of galaxy clustering in the redshift space, $\xi$, is described by a function of $\sigma$ and $\pi$, where $\sigma$ and $\pi$ are the transverse and the radial directions with respect to the observer. From the power spectrum $\hat{P}(k, \mu)$, we can compute the correlation function $\xi(\sigma, \pi)$ by Fourier transformation. The correlation function is generally expanded as

$$\xi(\sigma, \pi) = \int \frac{d^3k}{(2\pi)^3} \hat{P}(k, \mu) e^{i k \cdot s} = \sum_{\ell \text{ even}} \xi_\ell(s) \mathcal{P}_\ell(\nu),$$

(22)

with $\mathcal{P}_\ell$ being the Legendre polynomials. Here, we defined $\nu = \pi/s$ and $s = (\sigma^2 + \pi^2)^{1/2}$. The moments of the correlation function, $\xi_\ell(s)$, are defined in [11]. The contributions from moments higher than $\ell = 8$ will be ignored in our analysis because we are only interested in quasi-nonlinear scales where perturbation theory is applicable.

We compute theoretical templates for the moments $\xi_\ell(s)$ using the power spectrum given by Eq. (17). The shape of the initial spectra and the growth functions, $G_\delta$ and $G_\Theta$, are given by the best fit ΛCDM model from Planck 2013 [45]. We provide multiple templates with various $|f_{R0}| = (0, 10^{-6}, 3.2 \times 10^{-6}, 10^{-5}, 3.2 \times 10^{-5}, 10^{-4}, 3.2 \times 10^{-4}, 10^{-3}, 3.2 \times 10^{-3})$. For other values of $|f_{R0}|$, we interpolate these templates.

We now study the variation of $\xi(\sigma, \pi)$ due to the change of the growth function and growth rate. This variation was studied in the case of scale independent growth functions in [11] by varying $G_\delta(t)$ and $G_\Theta(t)$ in the RegPT template for ΛCDM. Following this approach, we first study the impact of having a scale dependent growth function or growth rate. For this purpose, we compute the correlation function $\xi(\sigma, \pi)$ using a ΛCDM template and replace the growth function $D_\delta^0$ or growth rate $D_\Theta^0$ by that in $f(R)$ gravity with $|f_{R0}| = 3.2 \times 10^{-5}$ and $|f_{R0}| = 3.0 \times 10^{-4}$, respectively.

For the scale dependent growth function $D_\delta^0$, the vari-
ation of ξ(σ, π) with a small |f_{R0}| = 3.2 × 10^{-5} is similar to the case of a scale independent enhancement of the growth function studied in [11]. Peak points on the BAO ring represented by a thick black solid curve in Fig. 2 move coherently along the circle in an anti-clockwise direction. The blue dashed contours in the left panel of Fig. 2 represent this variation. However, ξ(σ, π) with a larger |f_{R0}| = 3.0 × 10^{-4} varies differently from the scale independent case. Peak points on the BAO ring remain the same, while minima of BAO are deepened, shown as blue dotted contours in the same panel.

Next, we consider the variation of ξ(σ, π) due to the scale dependent growth rate D_ξ^θ. In the case of the scale independent growth rate, if G_θ increases or decreases, the anisotropic effects from higher order moments are visible in the plot of ξ(σ, π). The location of the crossing points between the contour levels and the BAO ring (thick solid) shifts clockwise or anti-clockwise slightly. The blue dashed contours in the right panel of Fig. 2 represent the variation of ξ(σ, π) with ΔD_ξ^θ for |f_{R0}| = 3.2 × 10^{-5} and |f_{R0}| = 3.0 × 10^{-4}. For |f_{R0}| = 3.0 × 10^{-4}, we can see that the peak positions are ‘squeezed’ along the BAO ring.

Having shown the individual effects of a scale dependent growth function and growth rate on the correlation function, we now present the correlation function ξ(σ, π) in f(R) gravity models. In Fig. 3, the correlation function with |f_{R0}| = 3.2 × 10^{-5} and |f_{R0}| = 3.0 × 10^{-4} are plotted as black dashed and black dotted contours, respectively. There is no variation of ξ(σ, π) up to |f_{R0}| ≲ 10^{-6}, and the correlation function is effectively equivalent to that of ΛCDM. When |f_{R0}| increases to |f_{R0}| ∼ 10^{-4}, we observe the deviation of ξ(σ, π) from ΛCDM and this deviation can be understood as the combined effect of the scale dependent growth function and growth rate shown in Fig. 2.

III. METHODOLOGY AND RESULTS

The observed clustering of galaxies in redshift space not only probes the density and velocity fields, i.e. the growth and gravity as discussed in the previous section, but also provides a useful tool to determine both the transverse and radial distances by exploiting the Alcock–Paczynski effect and the BAO scale. In galaxy redshift surveys, each galaxy is located by its angular coordinates and redshift. However, the correlation function, ξ(σ, π), is measured in comoving distances. Therefore a fiducial cosmological model is required for conversion into comoving space. We use the best fit ΛCDM universe to Planck 2013 data. The conversion depends on the transverse and radial distances involving D_A and H^{-1}. Instead of recreating the measured correlation function in comoving distances for each different model, we create the fiducial maps from the theoretical correlation function by rescaling the transverse and radial distances using D_A and H^{-1} and fit them to the observed correlation function. Therefore, when we fit the measured ξ(σ, π), the two distance parameters of (D_A, H^{-1}) are added to the structure formation parameter set of \{G_θ, G_φ, σ_p, |f_{R0}|, σ_f\} discussed in Sec. II.B.

A. Measured ξ(σ, π) using DR11

Our measurements are based on those previously presented in [13] which follows a similar procedure to [12]. Briefly, in our analysis we utilise data release DR11 of the Baryon Oscillation Spectroscopic Survey [BOSS; 46–48] which is part of the larger Sloan Digital Sky Survey [SDSS; 49, 50] program. From DR11 we focus our analysis on the Constant Stellar Mass Sample (CMASS) [51], which contains 690,826 galaxies and covers the redshift range z = 0.43 – 0.7 over a sky area of ~8,500 square degrees with an effective volume of V_{eff} ~ 6.0 Gpc^3. The CMASS galaxy sample is composed primarily of bright, central galaxies, resulting in a highly biased (b ~ 2) selection of mass tracers [52].

The redshift-space two-dimensional correlation function ξ(σ, π) of the BOSS DR11 galaxies was computed using the standard Landy-Szalay estimator [53]. In the computation of this estimator we used a random point catalogue that constitutes an unclustered but observa-
FIG. 4: The measured constraints on $f_{R0}$, and their robustness to various tests, are presented. The measured likelihood function appears in the top panels and the measured difference of $\chi^2$ is in the bottom panels. (Left panel) Results marginalizing over the scale independent growth rate $G_\Theta$ are shown by the black solid curve, while the constraints fixing $G_\Theta = 0.46$, given by the Planck concordance $\Lambda$CDM model, are blue dashed curves. The results for $f_{R0}$ do not depend appreciably on the scale independent behavior. (Right panel) The results also do not depend significantly on whether the initial power spectrum $P(k)$ used matches the Planck (black solid) or WMAP9 (black dashed) model. The blue dotted curve represents the results from analyzing galaxy clustering from $\Lambda$CDM mock catalogues, verifying that $|f_{R0}| \to 0$ is recovered in this case.

B. Tests of theoretical templates

When the conservative cut-off scales of $\sigma_{cut} = 40\, h^{-1}$Mpc and $s_{cut} = 50\, h^{-1}$Mpc are used for the analysis, the effective range of scale in Fourier space becomes $k < 0.1\, \text{Mpc}^{-1}$. The power spectra of $\Lambda$CDM and $f(R)$ gravity models are presented in this range of scale in Fig. 1. For the clustering scales considered in this likelihood analysis, there are no deviations from $\Lambda$CDM. This implies that $f(R)$ gravity models with $\log |f_{R0}| < \sim -6$ are effectively equivalent to $\Lambda$CDM in this analysis. We take a uniform prior on $\log |f_{R0}|$ between $-7$ and $-3$.

We first test our pipeline of analysis by checking whether it is possible to recover the $\Lambda$CDM limit $\log |f_{R0}| \lesssim -6$ using the mock catalogues based on $\Lambda$CDM. We use the 611 CMASS mock catalogues to measure central values of $\xi(\sigma, \pi)$ and fit our theoretical $f(R)$ templates to the observed correlation function. The measured likelihood function of $\log |f_{R0}|$ is presented as a blue dotted curve in the right panel of Fig. 4. The best fit $\log |f_{R0}|$ indeed lies within the $\Lambda$CDM limit of $\log |f_{R0}| \lesssim -6$. There are no mock galaxy catalogues based on $f(R)$ gravity available so we are not able to fully test our theoretical templates away from the $\Lambda$CDM limit. The perturbation theory predictions for the redshift space power spectrum in Fourier space were, how-

The covariance matrix was obtained from 600 mock catalogues based on second-order Lagrangian perturbation theory (2LPT) [54, 55]. The mocks reproduce the same survey geometry and number density as the CMASS galaxy sample. We obtain the covariance matrix using the same treatment presented in our previous works [12, 13].

We calculate the correlation function in 225 bins spaced by $10\, h^{-1}$Mpc in the range $0 < \sigma, \pi < 150\, h^{-1}$Mpc. However, at small scales, if the non-perturbative effect of FoG is underestimated, then the residual squeezing can be misinterpreted as a variation in $G_\Theta$ or indeed $f_{R0}$. We expect the FoG effect to be increasingly important at smaller scales, and so these measurements may be at risk of misestimation. We therefore impose a conservative cut on the measurements, excluding $\sigma_{cut} < 40\, h^{-1}$Mpc and $s_{cut} < 50\, h^{-1}$Mpc [12]. Indeed, [12] showed that cosmological parameter bias began to occur at smaller scales. This reduces the number of measurement bins in $\sigma$ and $\pi$ to $N_{bins} = 163$. 

We use a uniform prior on $\log |f_{R0}|$ between $-7$ and $-3$. 

We first test our pipeline of analysis by checking whether it is possible to recover the $\Lambda$CDM limit $\log |f_{R0}| \lesssim -6$ using the mock catalogues based on $\Lambda$CDM. We use the 611 CMASS mock catalogues to measure central values of $\xi(\sigma, \pi)$ and fit our theoretical $f(R)$ templates to the observed correlation function. The measured likelihood function of $\log |f_{R0}|$ is presented as a blue dotted curve in the right panel of Fig. 4. The best fit $\log |f_{R0}|$ indeed lies within the $\Lambda$CDM limit of $\log |f_{R0}| \lesssim -6$. There are no mock galaxy catalogues based on $f(R)$ gravity available so we are not able to fully test our theoretical templates away from the $\Lambda$CDM limit. The perturbation theory predictions for the redshift space power spectrum in Fourier space were, how-
ever, tested against N-body simulations for $f(R)$ gravity models and it was shown that the perturbation theory based template was able to reproduce the input value of $\log |f_{R0}|$ of the simulation in an unbiased way for $k < 0.1 \text{ Mpc}^{-1}$ [38].

C. Constraints on $f(R)$ gravity

We now present the results for constraints on $|f_{R0}|$, summarized in Table I. The Markov Chain Monte Carlo (MCMC) method is used to sample a probability distribution. The normalised distribution function of $\mathcal{L}/\mathcal{L}_{\text{max}}$ of the chain is given in terms of $\log |f_{R0}|$ in the top panel of Fig. 4, and the $\Delta \chi^2$ is shown in the bottom panel.

We begin by analysing our results while fixing $G_\Theta$ to the Planck $\Lambda$CDM model prediction of $G_\Theta = 0.46$. The measured $\log |f_{R0}|$ is then logit $|f_{R0}| < -3.87$ and $|f_{R0}| < -3.6$ at 68% and 95% confidence upper limits respectively. The lower index denotes the prior is hit – recall the $\Lambda$CDM limit of $|f_{R0}| \lesssim -6$, and the upper indices denote 68% and 95% confidence levels of $\log |f_{R0}|$ represented by unbracketed and bracketed numbers respectively. The distribution function and $\Delta \chi^2$ are presented by blue dashed curve in the left panel of Fig. 4.

The measured $\log f_{R0}$ after marginalising $G_\Theta$ and all other parameters is $-4.5^{+0.96(1.4)}_{-0.96(1.4)}$ as presented in Table I. The best fit $|f_{R0}| = 3.2 \times 10^{-5}$, and the upper bounds are $|f_{R0}| = 3.0 \times 10^{-4}$ and $8.0 \times 10^{-4}$ at 68% and 95% confidence levels, respectively. The observed $\xi(\sigma, \pi)$ is presented as black filled contours in Fig 3, and $\xi(\sigma, \pi)$ of the best fit $f(R)$ gravity model is represented as black dashed contours, which show a slightly better fit than $\xi(\sigma, \pi)$ of $\Lambda$CDM represented as black solid contours. The black solid curves in the left panel of Fig. 4 represents the distribution function (upper) and $\Delta \chi^2$ (lower). Note that $\log |f_{R0}| < -6$, i.e. $\Lambda$CDM, is within $\Delta \chi^2 < 1$ of our best fit value and so is wholly allowed by the current data. When $|f_{R0}|$ is larger than $10^{-4}$, $\xi(\sigma, \pi)$ becomes significantly different from the $\Lambda$CDM prediction. The black dotted contours in Fig. 3 represent $\xi(\sigma, \pi)$ with $|f_{R0}| = 3.0 \times 10^{-4}$ at 68% confidence bound. The difference from the measured $\xi(\sigma, \pi)$ can be observed.

In order to check the validity of our constraints, we test the effect of a different initial broadband shape of power spectra by using the WMAP9 best fit model as fiducial instead of Planck 2013. Although there is no significant difference within statistical allowances, the predicted initial broadband shape is slightly different in both cases. We would like to test whether this can cause a shift in the apparent $f_{R0}$. The black dashed curve in the right panel of Fig. 4 represents the likelihood function and $\Delta \chi^2$. The measured $\log |f_{R0}|$ using WMAP9 prior is $-4.6^{+0.81(1.2)}_{-0.81(1.2)}$, which is consistent with the result using Planck 2013 prior. Thus our results do not appear to be biased by the CMB priors.

Finally, since we measure $f_{R0}$ through its scale dependent effects, we consider a non-trivial scale dependent bias on our measurement. We model the bias as 

$$b(k) = b_0 \frac{1 + A_2 k^2}{1 + A_1 k^2}.$$ (23)

This simple bias model, when implemented in the formula in Eq. (17), can nicely fit the N-body data of the halo power spectrum and extract correctly the linear growth rate on scales very relevant to the current analysis [56, 57]. We find that the scale dependent bias parameters are determined as $A_2 = -0.8 \pm 4$ and $A_1 = -0.2 \pm 1.2$. Given the range of errors on these parameters and the range of wavenumbers $k \lesssim 0.1 \text{ Mpc}^{-1}$, the scale dependence of the bias is poorly determined. Since our established cutoff on small scales removes where scale dependent bias is expected to be most significant, all other measurements, including $f_{R0}$, remain similar to the results with scale independent bias. Thus the measurements shown in Table I are not modified much by a possible existence of this scale dependent galaxy bias.

D. Tests of $\Lambda$CDM model

Considering the constraints on the other fitting parameters, we can see if there is any evidence of deviations from $\Lambda$CDM model. Information on the late-time cosmological expansion is encoded in the distances along and transverse to the line of sight. The distance measurements are not affected by the scale dependent growth functions in $f(R)$ gravity models. In section III, we varied the scale dependent growth function $D_+^\delta$ and the growth rate $D_+^\delta$ and found that the BAO ring is invariant (see Fig. 2). As a consequence, there is little change in the measured $D_A$ and $H^{-1}$ from our previous result where scale independent growth functions are assumed [13]. The measured $D_A = D_A = 1428.0^{+30.1}_{-28.1} \text{ Mpc}$, and the measured $H^{-1}$ is $H^{-1} = 3157.5^{+190.0}_{-176.1} \text{ Mpc}$. The prediction of the $\Lambda$CDM model is indicated by the $x$ in Fig. 5, and the measured values, with uncertainties, are presented as filled contours in the top-left panel. The $\Lambda$CDM prediction is within the 1-$\sigma$ confidence level. The measured distances are consistent with the results using $\Lambda$CDM templates presented in the fifth column of Table I.

Although we vary galaxy bias $b$ in the fitting procedure, it is degenerate with the variation of $G_\delta$ on quasilinear scales. Thus as previously stated we can regard the combined measurement of $b$ and $G_\delta$ as a probe of $G_\delta$, whose measured value is $1.13^{+0.09}_{-0.08}$. Again there is little difference from the previous result of $G_\delta$ using $\Lambda$CDM templates presented in the fifth column of Table I.

When we fit the measured $\xi(\sigma, \pi)$, the amplitudes of the growth function and growth rate are determined at an effective scale $k_* \sim 0.07 \text{ h Mpc}^{-1}$ in our analysis. In $f(R)$ gravity the growth functions are enhanced in a scale dependent manner. Therefore if the amplitude of the growth function and growth rate at $k_*$ are tuned to be nearly the same as the $\Lambda$CDM model (e.g. to agree with

TABLE I: The Planck best-fit ΛCDM predictions and the measured values with their 1-σ confidence level errors are shown for the parameters $D_A, H^{-1}, G_b, G_\Theta, \sigma_b, \log |f_{R0}|$. The Planck ΛCDM data does not predict the phenomenological parameters $G_b$ and $\sigma_p$. The last two columns show the measured values in the test cases when $G_\Theta$ is fixed to the Planck prediction 0.46, or $f_{R0} = 0$, respectively.

...data, then the measured $G_b$ and $G_\Theta$ must be smaller to offset the enhancement. So for appreciable $\log |f_{R0}|$ we expect an anti-correlation between $\log |f_{R0}|$ and $G_\Theta$. This is visible in the left panel of Fig. 6 for the larger values of $\log |f_{R0}|$. Since the best fit $\log |f_{R0}|$ is slightly larger than the LCDM bound, this may contribute to why the measured $G_\Theta = 0.39^{+0.09}_{-0.09}$ is smaller than the ΛCDM result. However, the prediction of ΛCDM presented by the $x$ in Fig. 5 is still within the 68% CL measured $G_\Theta$ contours.

Finally, we show the measured FoG effect in terms of $\sigma_p$ in the right panel of Fig. 6. Again we do not find any significant change from the previous result using ΛCDM templates.

IV. CONCLUSION

We have investigated the effect of $f(R)$ gravity on the redshift space correlation function $\xi(\sigma, \pi)$ using a consistent modified gravity perturbation theory template that also includes some nonlinear and chameleon screening effects. The scale dependent growth functions $D^+_{\Theta}$ and $D^+_{\Theta}$ alter at late times the initial broadband shape probed by the CMB experiments, but the comoving scale of the sound horizon is not affected, and we find the measured BAO ring remains the same as in ΛCDM and so the distances $D_A$ and $H^{-1}$ do also. The effect of modified gravity would be most evident in the redshift space distortions and hence anisotropy of the clustering.

We demonstrated how $\xi(\sigma, \pi)$ alters with increments of $D^+_{\Theta}$ and $D^+_{\Theta}$ for small and large $|f_{R0}|$ values in Fig. 2. This shifts the correlation amplitude at the BAO scale and other scales compared with the scale independent growth functions case. At small $|f_{R0}| = 3.2 \times 10^{-5}$, there is no significant anisotropic variation with $\Delta D^+_{\Theta}$; the peak locations move nearly coherently anti–clockwise along the BAO ring. But when $|f_{R0}|$ increases and it becomes larger than $|f_{R0}| = 10^{-4}$, the effect of anisotropic amplification dominates and $\xi(\sigma, \pi)$ departs from ΛCDM.

Using the BOSS DR11 data we measure the anisotropic $\xi(\sigma, \pi)$, presented as blue filled contours in Fig. 3, and find a best fit $|f_{R0}| = 3.2 \times 10^{-5}$, with an upper bound $|f_{R0}| < 3.0 \times 10^{-4}$ at the 68% confidence level; the lower 68% confidence level is consistent with ΛCDM. We also note an anticorrelation between $f_{R0}$ and the scale independent growth rate $G_\Theta$ that could reduce the measured value of $G_\Theta$ despite the enhancement of growth due to $f(R)$ gravity.

We tested our data analysis pipeline by applying it to ΛCDM mock catalogues, and we reproduced the ΛCDM bound of $|f_{R0}| \lesssim 10^{-6}$. We also tested the robustness of our results against the change of the CMB prior. There is a slight difference in the measured early broadband shape of spectra between WMAP9 and Planck 2013, but the measured $|f_{R0}|$ is independent of this difference. In addition, we tested the effect of the scale dependent bias on the measured $|f_{R0}|$. Again our results were shown to be insensitive to a possible scale dependent galaxy bias.

Although the best fit value of $|f_{R0}|$ is away from ΛCDM bound, the deviation is insignificant with $\Delta \chi^2 \lesssim 1$, and it is indistinguishable from ΛCDM model. The comparison of the measured minimum $\chi^2_{\text{min}}$ when marginalising or fixing $\log |f_{R0}|$ to zero, and marginalising or fixing the scale independent growth rate to the Planck best fit, are presented in last row of Table I. With future wide, deep spectroscopy experiments such as Dark Energy Spectroscopy Instrument (DESI) we will be able to use the redshift space correlation function $\xi(\sigma, \pi)$ to probe $f(R)$ gravity below $|f_{R0}| < 10^{-4}$ – and other scale dependent modified gravity – and test general relativity more stringently.

Appendix A: Power spectrum and bispectrum calculations in RegPT

In this appendix, based on the RegPT treatment, we summarize the expressions for the basic ingredients needed to compute the redshift-space power spectrum in $f(R)$ gravity model [Eq. (17)]. The RegPT scheme is based on a multipoint propagator expansion, and with this scheme any statistical quantities consisting of density and velocity fields are built up with multipoint propagators, in which nonperturbative properties of gravitational growth are wholly encapsulated [58]. Making use of the analytic properties of the propagators, a novel regularized treatment is constructed with the help of the standard PT kernels [59], showing that the proposed scheme can be used to give a percent-level prediction of the power spectrum and correlation function in the weakly nonlinear regime in both real and redshift spaces [42, 44].

Let us define a two-component multiplet, $\Psi_a(\mathbf{k}; t) \equiv (\delta(\mathbf{k}; t), \Theta(\mathbf{k}; t))$. Then, the power spectra of $\Psi_a$ valid at one-loop order are expressed as

$$P_{ab}(\mathbf{k}; t) = \Gamma^{(1)}_a(\mathbf{k}; t) \Gamma^{(1)}_b(\mathbf{k}; t) P_0(\mathbf{k}) + 3 \int \frac{d^3 q}{(2\pi)^3} \Gamma^{(2)}_a(q, \mathbf{k} - q; t) \Gamma^{(2)}_b(q, \mathbf{k} - q; t) \times P_0(q) P_0(|\mathbf{k} - q|), \quad (A1)$$

where $P_0$ is the power spectrum of initial density field $\delta_0$. The functions $\Gamma^{(n)}_a$ are the multipoint propagators. For the one-loop calculation, the relevant expressions for the regularized propagators, which reproduce both the resummed behavior at high-$k$ and standard PT results at low-$k$, are given by

$$\Gamma^{(1)}_a(\mathbf{k}; t) = \left[ F^{(1)}_a(\mathbf{k}; t) \left\{ 1 + \frac{k^2 \sigma^2}{2} \right\} \right]$$

$$+ 3 \int \frac{d^3 q}{(2\pi)^3} F^{(3)}_a(q, \mathbf{k} - q; t) P_0(q) e^{-k^2 \sigma^2/2} \quad (A2)$$

$$\Gamma^{(2)}_a(q, \mathbf{k} - q; t) = F^{(2)}_a(q, \mathbf{k} - q; t) e^{-k^2 \sigma^2/2}, \quad (A3)$$

where the functions $F^{(n)}_a$ are the standard PT kernels, sometimes written as $F^{(n)}_a = (F_n, G_n)$ [43]. Note that the leading-order kernel $F^{(1)}_a$ is related to the linear
The propagators $\Gamma_a(1)$ and $\Gamma_a(2)$ in the above are also evaluated with the tree-level expressions:

$$\Gamma_{a,\text{tree}}(k_1, \ldots, k_n; t) = F_a^{(n)}(k_1, \ldots, k_n; t) e^{-k^2 \sigma_a^2/2},$$  \hfill (A7)

where $k = |k_1 \ldots n|$. Note finally that while the power spectrum and bispectrum given above are quite general and valid in any model of modified gravity, the expressions for the propagators in RegPT might receive some corrections. This issue has been discussed in detail in Ref. \[10]. However, it has been found that within the $f(R)$ gravity model, any corrections due to the modification of gravity are very small and can be neglected at the large scales of our interest. Hence, all the expressions given above are basically the same as those in GR, except for the standard PT kernels, $F_a^{(n)}$. Unlike the GR case, the time and scale dependence of $F_a^{(n)}$ are not separately treated in $f(R)$ gravity model. The functional form of $F_a^{(n)}$ is thus non-trivial, even if the deviation of gravity from GR is small. In this paper, on the basis of Eqs. (2), (3), (6) and (7), we derive the equations that govern the standard PT kernels. Solving these equations numerically, we construct the kernels that are tabulated as function of wave vectors [60].
