Abstract. We investigate the impact of galactic mass loss triggered by ram-pressure stripping of cluster galaxies on the evolution of the intra-cluster medium (ICM). We use combined N-body and hydrodynamic simulations together with a phenomenological galaxy formation model and a prescription of the effect of ram-pressure stripping on the galaxies. We analyze the effect of galaxy – ICM interaction for different model clusters with different masses and different merger histories. Our simulations show that ram-pressure stripping can account for $\sim 10\%$ of the overall observed level of enrichment in the ICM within a radius of 1.3 Mpc. The efficiency of metal ejection of cluster galaxies depends at the first few Gyr of the simulation mainly on the cluster mass and is significantly increased during major merger events. Additionally we show that ram-pressure stripping is most efficient in the center of the galaxy cluster and the level of enrichment drops quite fast at larger radii. We present emission weighted metallicity maps of the ICM which can be compared with X-ray observations. The resulting distribution of metals in the ICM shows a complex pattern with stripes and plumes of metal rich material. The metallicity maps can be used to trace the present and past interactions between the ICM and cluster galaxies.

Key words. Galaxies: clusters: general – Galaxies: abundances – Galaxies: interactions – Galaxies: ISM – X-ray: galaxies: clusters

1. Introduction

The presence of an embedding medium has an influence on the evolution of galaxies. This effect will be most important in high density environments like those of galaxy clusters. One mechanism how galaxies can lose parts of their inter-stellar medium (ISM) due to interaction with their surroundings is ram-pressure stripping (Gunn & Gott 1972). Observations show that this mechanism is at work in several galaxies in the Virgo cluster (e.g. Cayatte et al. 1990, Kenney et al. 2004, Vollmer et al. 2001) and in the Coma cluster (Bravo-Alfaro et al. 2000, 2001). Galaxies subject to ram-pressure stripping will lose parts of their ISM which has been enriched with heavy elements by their stars. This will have an impact on the chemical abundance of the surrounding intra-cluster medium (ICM). X-ray observations here revealed that the ICM is highly enriched with heavy elements (about 0.3 solar in iron: e.g. Fukazawa et al. 1998). With the recent X-ray satellites Chandra and XMM it is even possible to study the 2D distribution of the heavy elements (e.g. Schmidt et al. 2002, Furusho et al. 2003, Sanders et al. 2004, Fukazawa et al. 2004, Hayakawa et al. 2004). As heavy elements cannot be produced in the ICM itself, part of this medium seems to originate from cluster galaxies. Although ram-pressure stripping of cluster galaxies will contribute to the chemical enrichment of the ICM several other mechanisms like galactic winds (de Young 1975), galaxy-galaxy interaction (e.g. Kapferer et al. 2005a) or intra-cluster supernovae (Domainko et al. 2004) will also play an important role. Each mechanism will result in a characteristic distribution of metal rich material in the ICM, so with the distribution of heavy elements the origin of the metals can be constrained. Observational evidence for some chemical enrichment due to ram-pressure stripping has been found: high metallicity regions in the ICM of the galaxy cluster Abell 1060 stripped from cluster galaxies were measured (Hayakawa et al. 2004). Indeed it has been argued that ram-pressure stripping can act as an enrichment agent over a long period of cluster evolution (Finoguenov et al. 2000) and at low redshifts (Oosterloo &
van Gorkom (2005). Hence the metals are a good tracer for the present and past interaction processes between galaxies and the ICM.

The high level of enrichment in the ICM has triggered a lot of discussion about the origin of these metals. Several groups have investigated the chemical evolution of the ICM with extensive numerical simulations. De Lucia et al. (2004) and Nagashima et al. (2005) investigated this problem using N-body simulations combined with semi-analytic galaxy formation and evolution. They conclude that most of the metals are ejected by supernova-driven galactic winds mainly from the most massive galaxies and they find that there is a mild chemical evolution since $z = 1$. They do not predict the distribution of the metals in the ICM. Tornatore et al. (2004) use a smooth particle hydrodynamic simulation and emphasize the contribution of different supernova types to the enrichment but do not investigate in detail the influence of different ejection mechanisms. Their results indicate that the simulations still lack a feedback mechanism which quenches star formation and transports metals at low redshifts.

In contrast to these papers our calculations emphasize the transport mechanisms of the enriched material and we use a shock capturing method for the hydrodynamic treatment (see also Schindler et al. 2005, Domainko et al. 2005). Furthermore we are able to trace the distribution of the enriched material lost by the cluster galaxies. In this paper we investigate the impact of the enrichment of the ICM by ram-pressure stripping of cluster galaxies. Other processes are studied elsewhere (e.g. Kapferer et al. 2005, 2005c).

The effect of ram-pressure stripping on individual galaxies was studied analytically and numerically by several groups. A first analytical criterion for ram-pressure stripping was already given by Gunn & Gott (1972). According to this criterion galaxies lose material if the force due to ram-pressure stripping exceeds the restoring gravitational force of the galaxy. One result of this consideration is the presence of a stripping radius in ram-pressure affected galaxies outside which the galactic gravitational potential is too shallow to prevent the ISM from being stripped. Various authors studied this stripping radius with respect to acting ram-pressure and galaxy properties (e.g. Abadi et al. 1999, Vollmer et al. 2001, Roediger & Hensler 2005). In general these authors found a reasonable agreement between the analytically estimated stripping radius and the stripping radius determined by numerical simulations. Additionally Roediger & Hensler (2005) discussed the most appropriate analytical description with respect to the numerical results. These authors supplemented the estimate used by Mori & Burkert (2000) which compares the thermal ISM pressure with ram pressure. For the case of a constant ram pressure acting on the galaxy Roediger & Hensler (2005) found the closest coincidence between analytical description and numerical simulation for the estimate introduced by Mori & Burkert (2000). For the case of a time dependent ram pressure like it is the case for galaxies moving on non-circular orbits through a galaxy cluster, Vollmer et al. (2001) concluded that the Gunn & Gott (1972) criterion adopted to the galactic inclination angle can explain the HI deficiency of the galaxies in the Virgo cluster. Further numerical simulations for ram-pressure stripping on galaxy scales were presented in several papers (e.g. Abadi et al. 1999, Quilis et al. 2000, Mori & Burkert 2000, Vollmer et al. 2001, Toniazzo & Schindler 2001 and Roediger & Hensler 2005). In contrast to those papers we present simulations showing the impact of ram-pressure stripping of all cluster galaxies on the ICM. We obtain simulations on galaxy cluster scale and compute the efficiency and time dependence of galactic mass loss triggered by ram-pressure stripping. In this paper we focus on the effect of ram-pressure stripping on the metal enrichment of the ICM. The effect on the affected galaxies will be shown in van Kampen et al. (in prep.).

This paper is organized as follows: In Section 2 we present the numerical method used. In Section 3 we describe the general simulation setup and the properties of the model clusters. In Section 4 we show our results. And in Section 5 we summarize and discuss the results obtained.

2. Numerical Method

We use the same general simulation setup as described in Schindler et al. (2005).

2.1. N-body simulations

Our starting point is a model for the dark matter distribution within and around the cluster, for which we use N-body simulations. The N-body code is that of Barnes & Hut (1986), adapted to include a halo formation recipe that prevents over merging on small scales (van Kampen et al. 1999). This paper assumes a ΛCDM cosmology, with $Ω_Λ = 0.7$, $Ω_m = 0.3$, $h = 0.7$, and $σ_8 = 0.93$. Initial conditions are produced using the constrained random field method of Hoffman & Ribak (1991), as implemented by van de Weygaert & Bertschinger (1995). Constraints are put on the smoothed density field in the form of peak heights for a Gaussian window of 6 Mpc, which produce a rich cluster in the center of the box for peaks above three times the r.m.s. density fluctuation at that scale. The N-body simulations are obtained within a box of 46 Mpc (for $H_0 = 70$ km s$^{-1}$ Mpc$^{-1}$) with 64$^3$ particles. The softening length of the N-body simulation is 20 kpc which is also the resolution of the dark matter distribution. The whole cluster is described by tens of thousands of dark matter particles, which can easily resolve the radial structure of the cluster as well as substructures. The halos of the galaxies are represented by groups of particles with a minimum of 10 particles with a half-mass radius of the smallest halo of 30 kpc. For these galactic halos we assume an isothermal profile. The galactic dark matter halo gravitation is treated without any spatial details by simply applying the gravitational potential.
2.2. Hydrodynamic treatment

For the hydrodynamic part of the simulation we use a shock capturing, grid based scheme (PPM, Collela & Woodward 1984, Fryxell et al. 1989). PPM is a higher order version of the Riemann solver based Godunov method (Godunov 1959). This allows us to study all the dynamical effects in the ICM connected to subcluster mergers with high accuracy. To achieve high resolution at the cluster center where most of the stripping is expected to happen and also to trace infalling gas-rich galaxies from outside the cluster, we compute our simulation on multiple refined grids (Ruffert 1992). Radiative cooling of the ICM is treated according to the cooling functions given by Sutherland and Dopita (1993). Metallicity is used as a tracer to follow the gas which is lost by the cluster galaxies. Metallicity is handled as a single quantity therefore we do not distinguish between different chemical elements (like iron and α elements) but assume solar composition. Additionally to the bulk motion of the ICM, diffusion should also further disperse the stripped gas. In the presented paper we are mainly interested in the distribution of the enriched material therefore only the effect of diffusion on heavy nuclei is investigated. Diffusion strongly depends on the mass and the charge of the involved nuclei (see Lanz 1999, Chapter 3.1.2 and 3.1.5). The most prominent detection of metals in the ICM is connected to the presence of iron. Diffusion will spread iron in the ICM within the Hubble time on length scales of less than 100 kpc. Therefore this process is inefficient in further distributing iron on galaxy cluster scales.

2.3. Galaxy formation

The halo formation recipe that is part of the N-body code allows us to easily generate halo merging histories, and also the merging histories of the galaxies occupying the halos. Simple prescriptions for gas cooling, star formation and feedback mechanisms make up our phenomenological galaxy formation model, which is an improved version of the model of van Kampen et al. (1999). Important for the context of this paper is the inclusion of a disk model, which is similar in nature to that of Mo, Mao & White (1998), but with the inclusion of an observed threshold for star formation in disks (Kennicutt 1989, Martin & Kennicutt 2001). The adoption of the Mo, Mao & White approximations produce a gas and stellar disk with the same exponential scale-length, but different cut-off radii and central densities. Our modeling of the metallicity evolution is described in two papers: in Kapferer et al. (2005b) the coupled circuit of the evolution of the stellar, cold and hot gas components is given, whereas the chemical evolution of the stellar populations can be found in van Kampen et al. (1999). The star formation history of each galaxy is constrained by its merger history. Halo-halo mergers and galaxy-galaxy mergers trigger short bursts of star formation. Metals which are produced in disk stars can either be added to the cold gas disk or can be ejected directly into the hot gas, or into the ICM for cluster galaxies that have their hot gas halos stripped. We choose the extreme scenario to add metals produced in disk stars to the cold gas in the disk which can then be stripped off through ram-pressure stripping. We do not replenish the stellar disk from stellar ejecta along the path of a galaxy: star formation is truncated ‘forever’ if the whole gas disk is stripped, and the galaxy ends up as an S0 in case the stellar disk is prominent enough, and as an elliptical if it is not. In reality, some stellar mass loss will occur also after the star formation has ended. Intermediate mass stars will eject material in form of AGB winds and supernova Ia ejecta.

2.4. Ram-pressure stripping

To calculate the mass loss of cluster galaxies due to ram-pressure stripping we follow the classical Gunn & Gott (1972) criterion because Vollmer et al. (2001) concluded that for non circular orbits the Gunn & Gott (1972) criterion additionally extended for the inclination angle of the galaxy can explain the HI deficiency of galaxies located in the Virgo cluster. According to this criterion material is lost by a galaxy if the force due to ram-pressure, exceeds the restoring gravitational force. The Gunn & Gott (1972) criterion is given by:

\[ P_{\text{ram}} \geq 2\pi G \sigma_{\text{star}} \sigma_{\text{gas}} \]

with

\[ P_{\text{ram}} = \rho_{\text{ICM}} v_{\text{gal}}^2 \]

\[ P_{\text{ram}} \] is the ram-pressure, \( G \) is the gravitational constant, \( \sigma_{\text{star}} \) is the stellar surface density, \( \sigma_{\text{gas}} \) is the surface density of the gas, \( \rho_{\text{ICM}} \) is the density of the ICM and \( v_{\text{gal}} \) is the velocity of the galaxy relative to the ICM. We calculate the mass loss of the cold ISM disks of spiral galaxies. We assume that the galaxies consist of an exponential stellar disk and an exponential gas disk. Due to the phenomenological galaxy formation model (see Sect. 2.3) the scale length of the stellar disk and gas disk are equal but the central densities are different:

\[ \sigma_{\text{star, gas}} = \frac{M_{\text{star, gas}}}{2\pi R_0^2} e^{-r/R_0} \]

\[ M_{\text{star}} \] is the mass of the stars, \( M_{\text{gas}} \) is the mass of the gas and \( R_0 \) is the disk scale length. With these assumptions we can analytically determine a stripping radius \( R_{\text{strip}} \):

\[ x = 0.5 \times \ln \left( \frac{G M_{\text{star}} M_{\text{gas}}}{v_{\text{gal}}^2 \rho_{\text{ICM}} 2\pi R_0^4} \right) \]

with

\[ x = \frac{R_{\text{strip}}}{R_0} \]

Material which is located outside this stripping radius is then lost by the galaxy. The validity of this treatment
was shown with numerical simulations and with comparisons with Virgo cluster galaxies by Abadi et al. (1999). The amount of cold gas which can be kept by the galaxy \( M(R_{\text{strip}}) \) is:

\[
M(R_{\text{strip}}) = M_{\text{gas}} \left[ 1 - (x + 1) e^{-x} \right]
\]

Consequently the amount of gas \( M_{\text{strip}} \), which is stripped off the galaxy is then:

\[
\frac{M_{\text{strip}}}{M_{\text{gas}}} = (x + 1) e^{-x}
\]

Mass loss due to ram-pressure stripping should in principle also be influenced by the inclination angle of the affected galaxy. The impact of the inclination angle of the galaxy on the stripping process was investigated by Quilis et al. (2000) with numerical simulation. Those authors find that there is only little dependence of the effectiveness of ram-pressure stripping for galaxies which move close to face on through the ICM. For example a galaxy moving at an inclination of 20° to the direction of motion suffers as much stripping as face on encounters (Quilis et al. 2000).

There are, however, also arguments which suggest a certain impact of the inclination angle on the stripping process. The column density of the gas that has to be pushed by the momentum transfer from the ICM grows with the cosine of the inclination angle. Also the area of ram pressure which is acting on the unit area of an inclined galaxy scales with the same factor. In this work, due to the lack of more elaborate considerations and for simplicity, mass loss of galaxies moving inclined as opposed to face on through the ICM is scaled with the cosine of the inclination angle with respect to the mass loss derived for an uninclined galaxy. Stripped material is added locally to the ICM and is removed from the galaxies. Note that this treatment can be regarded as an upper limit of the galactic mass loss due to ram-pressure stripping as it was shown that a minor fraction of stripped material might be reaccreted back by the stripped galaxy (see Vollmer et al. 2001). The stripping condition is evaluated at every time step of the cluster scale hydrodynamic simulation. The mass loss of the galaxies is calculated according to the actual properties of the galaxies as it is derived by the galaxy evolution model (see Sect. 2.3). We also assume that the gas disk remains truncated after a stripping event. This means that galaxies are only further stripped when they experience increasing ram-pressure. The stripped ISM in the outer part of the disks should in principle be replaced by supernovae and stellar winds. However observations show that star formation is truncated in ram-pressure affected cluster galaxies (e.g. Koopmann & Kenney 2004). Hence only a passively aging stellar population with a significantly reduced mass loss is present in regions of the galactic disk where the ISM is stripped off. Although as already mentioned in Sect. 2.3 intermediate mass stars will eject some enriched material, we do not take this additional effect into account.

After the stripping radius is reached the mass loss continues due to Kelvin - Helmholtz instabilities (Mori & Burkert 2000). Since Roediger & Hensler (2005) argued that the contribution to the mass loss caused by Kelvin - Helmholtz instabilities is small, we do not account for this mass loss in our further calculations.

Observations of nearby spiral galaxies show that abundance gradients are present in their disks (see e.g. Henry & Worthey 1999). The slopes of the gradients depend on the morphology of the galaxy (Henry & Worthey 1999). This feature exhibits a certain influence on the enrichment of a surrounding medium due to ram-pressure stripping. For the case of galactic metallicity gradients which flatten in the outer parts of the galaxy we expect only a limited effect on the proposed enrichment process. In this case the mean abundance of the gas is close to the abundance of the bulk of the gas which is located at large galactic radii. But this issue certainly demands further analysis. As a first approach we do not consider galactic abundance gradients in our simulations. In future more refined studies we will investigate the actual impact of galactic abundance gradients on the ICM enrichment.

### 2.5. Supersonic galaxies

In our simulations several galaxies move with a velocity relative to the embedding medium which is higher than the local sound velocity. In this case of supersonic galaxies the classical Gunn & Gott (1972) approach has to be modified. Supersonic galaxies will form bow shocks in front of them and the stripping criterion has to be applied to the conditions behind these bow shocks. Hydrodynamic quantities behind the bow shocks can be calculated as functions of the quantities in front of the bow shock according to the Rankine-Hugoniot conditions for all Mach numbers \( M > 1 \). Using the equation of continuity at the bow shock we can calculate the ratio between densities and velocities in front of and behind the bow shock:

\[
\frac{\rho_1}{\rho_2} = \frac{v_2}{v_1}
\]

Here \( \rho \) are the densities, \( v \) are the velocities and subscript 1 stands for quantities in front of the shock and subscript 2 stands for quantities behind the shock. For the ram-pressure in front of and behind the shock this leads to:

\[
P_{\text{ram,1,2}} = \rho_{1,2} v_{1,2}^2
\]

As the velocities behind the shock are smaller than the velocities in front of the shock also the ram-pressure will be smaller behind the shock due to its dependence on the square of the velocity. This means that for supersonic galaxies ram-pressure stripping is less efficient than the classical Gunn & Gott (1972) approach would suggest. We calculate the Rankine-Hugoniot condition for the actual Mach number of each individual galaxy. Therefore this treatment is also correct for supersonic galaxy motion in galaxy clusters with low Mach numbers. The effect
is most pronounced for very fast galaxies. In the case of \( v_{\text{gal}} \gg c_s \) with \( v_{\text{gal}} \) being the velocity of the galaxy relative to the ICM and \( c_s \) the local sound velocity and treating the ICM as an ideal gas with \( \gamma = 5/3 \) with \( \gamma \) being the ratio of specific heats, the ram pressure is by a factor of 4 lower behind the galactic bow shock than in front of the bow shock. An additional effect in supersonic ram-pressure stripping could come from the fact that the bow shock is bent according to the Mach number. Since our simulations are performed on galaxy cluster scale we cannot resolve individual galaxies and the form of their bow shocks. But it is expected that for low Mach numbers the opening angle of the bow shock is quite large. Therefore we do not take into account the effect of the bending of the bow shock. It is also important to mention that Roediger & Hensler (2005) found a better agreement between analytic estimates and numerical simulations of ram-pressure stripping if a Rankine-Hugoniot correction is applied.

3. Simulation set up and model clusters

We run the hydrodynamic simulation on four levels of nested grids centered on the cluster centers, the largest grid being (20 Mpc)\(^3\) and the smallest (2.5 Mpc)\(^3\). Each of the nested grids has a resolution of 128\(^3\) grid cells. We start the hydrodynamic simulation at a redshift of \( z = 1 \) for numerical reasons and follow the evolution of the ICM to a redshift of \( z = 0 \). This is the time interval of interest as ram-pressure stripping is expected to be most efficient after the galaxy clusters have formed.

In order to test the impact of ram-pressure stripping on different galaxy clusters we choose model clusters which span a wide range of masses and evolutionary histories. Our model clusters contain no cD galaxies and do not feature cooling cores at their centers. The model clusters are as follows:

**Model cluster 1**: This is the most massive cluster of our sample. The final total cluster mass at \( z = 0 \) inside a radius of 3 Mpc is \( 1.3 \times 10^{15} M_\odot \). This cluster experiences only small merger events after \( z = 1 \).

**Model cluster 2**: This is the least massive cluster in our sample. The final total cluster mass at \( z = 0 \) inside a radius of 3 Mpc is \( 7.4 \times 10^{14} M_\odot \). This cluster undergoes a major merger with a mass ratio of 1:3 at a redshift of 0.5. Additionally it features the infall of several smaller subystems.

**Model cluster 3**: This cluster has a mass of \( 8.7 \times 10^{14} M_\odot \) inside a radius of 3 Mpc at the final redshift of \( z = 0 \). It undergoes two minor mergers.

4. Results

4.1. Total amount of stripped metals

The first quantity of interest is the total amount of material which is ejected into the ICM by ram-pressure stripping. As ram-pressure stripping is a process dependent on the environment it is expected that the total amount of material stripped from the affected cluster galaxies will depend on the properties of the cluster. Galaxy clusters with higher masses strip galaxies more efficiently than galaxy clusters with lower masses. This is due to a higher ICM density and to a higher velocity dispersion in high mass systems.

In our simulation we derive the total amount of metals stripped from the cluster galaxies. By comparing the total mass of metals stripped we test the dependence of galactic metal loss on cluster mass. Indeed we find that the total mass loss is highest in the high mass cluster (model cluster 1) and lower in the low mass clusters. We see that in the high mass cluster in our sample (model cluster 1) the total amount of metals ejected into the ICM is about four times higher than in the model clusters with lower mass.

![Fig. 1. Temporal metallicity evolution \( M_{\text{metals}}/M_{\text{ICM}} \) in the different model clusters. The values are given for all galaxies which are located inside the central (2.5 Mpc)\(^3\) of our simulations. For an explanation of the different slopes for the different model clusters see Sect. 4.2.](image-url)

Another interesting quantity is the fraction of the ICM which actually originates from cluster galaxies and is lost by them due to ram-pressure stripping. To investigate this question, we compare the mass of the hot ICM, which in our simulations has never been inside any galaxy, to the amount of material which has actually been lost by the galaxies (see Fig. 2).

We find that about 10% of the ICM in the central (2.5 Mpc)\(^3\) of our simulation originates from ram-pressure affected galaxies. The fraction of the ICM which originates from cluster galaxies is comparable for all our model clusters (see Fig. 2). This result is expected since in the high mass cluster also the mass of the ICM is larger than in the clusters with lower mass. Mixing then the ICM in the high mass cluster with a larger amount of material which
is lost by the galaxies results in a comparable fraction of lost ICM to primordial ICM as in the low mass clusters.

4.2. Mass loss rate due to ram-pressure stripping

We now investigate the combined mass loss rate of all cluster galaxies as a function of time. It is interesting to mention that the time evolution of the mass and metal ejection is different for different model clusters (see Fig. 1 and Fig. 2). With the analysis of the total mass loss rate of all cluster galaxies as a function of time we further explore this behavior. The mass loss of all cluster galaxies as a function of time is shown in Fig. 3 and Fig 4.

We find that in the first 3 Gyr the mass loss rate in the high mass cluster (model cluster 1) is about an order of magnitude higher than the mass loss rate in low mass clusters. There is also a prominent peak at the start of the simulation in model cluster 1. This first peak originates from the mass loss of gas rich galaxies which experience the effect of ram-pressure for the first time by switching on the calculation. After 3 Gyr the mass loss of the galaxies in the high mass cluster drops significantly. We interpret this as an effect of cluster mass. Stripping in the high mass cluster can reduce the size of the gas disks of galaxies quite fast and then this mechanism becomes less efficient (see Fig. 3).

The situation is very different for the merging cluster (model cluster 2). In the case of a cluster experiencing mergers the prehistory of ram-pressure is also followed within the infalling subsystems. In this system mass loss starts at a quite small rate but between 3 Gyr and 5 Gyr the rate rises by an order of magnitude. In this time interval also the major cluster merger happens. Here we see the influence of the merger history on the evolution of the mass loss rate due to ram-pressure stripping (see Fig. 4). At about 6 Gyr several galaxy groups fall towards the cluster center and the mass loss rate increases again. Subcluster merger can raise the stripping rate by an enhanced velocity dispersion, increased ICM density and due to infall of gas rich galaxies onto the main cluster. The strongly enhanced mass loss rate during subcluster mergers is also the reason for the quite different slopes for model cluster
Fig. 5. Emission weighted metallicity profiles of the three model clusters at a redshift of $z = 0$. Ram-pressure stripping can account for the observed metallicity in the central 100 kpc in all simulations, but at larger radii other processes than ram-pressure stripping have to contribute to the enrichment of the ICM.

In the calculated profiles we clearly see the highest level of chemical enrichment of the ICM at the cluster center. At the cluster center the environmental impact on the galaxies will be most important so it is expected that there the enrichment is most pronounced. In the central 100 kpc ram-pressure stripping can account for an enrichment of about 0.2 solar which is close to the observed value. At larger radii the chemical abundance drops very quickly and other processes than ram-pressure stripping must contribute to the chemical evolution of the ICM.

4.5. Distribution of enriched material

Metallicity can be used as a tracer to identify the location of the gas which was lost by cluster galaxies. To investigate the distribution of the enriched material and to compare our simulations with observed galaxy clusters, we obtain emission weighted metallicity maps. For a discussion on the effect of diffusion on the metallicity distribution see Sect. 2.2. In contrast to the full 3D distribution of the metal rich areas, enriched material located in high density regions is much more pronounced in emission weighted metallicity maps. The emission weighted metallicity maps clearly show a complex pattern of the chemically enriched material (see Fig. 6). A nonuniform distribution of the enriched material is in good agreement with recent observations (e.g. Hayakawa et al. 2004).

In all the model clusters we see stripes of metal rich material which were left behind by infalling galaxies. Some of them are even several hundred kpc long. It is interesting to note the similarity of these stripes with the plume of stripped gas observed at the center of the Virgo cluster in HI (Oosterloo & van Gorkom 2005) and with the trails of ionized gas behind two galaxies in Abell 1367 (Gavazzi...
Fig. 6. Emission weighted metallicity maps of the model cluster. The size of the boxes is 5 Mpc on a side. The level of enrichment is given in solar units.
et al. [2001]. In contrast to these observations, material in our computed enriched stripes is already mixed with the hot ICM. Evaporation of stripped gas clouds at the center of our model cluster \( (T_{\text{ICM}} \sim 10^8 \, \text{K}, \, n_{\text{ICM}} \sim 10^{-3} \, \text{cm}^{-2}) \) can occur within \( 10^7 \, \text{yr} \) (Vollmer et al. [2001]), which is the typical time step of the hydrodynamic simulation. Stripped gas from cluster galaxies is indeed seen in the hot \( (T = 10^8 \, \text{K}) \) ICM of the Coma cluster (Finoguenov et al. [2004]) in X-ray observations.

The non-merging model cluster 1 shows metal maps with an almost spherically symmetric appearance. There is only little evolution between 4.0 Gyr and 7.9 Gyr in our simulation (see Fig. 6 two panels at the top). This is in good agreement with the results of Section 4.2. In contrast model cluster 2 shows a very complex distribution of the enriched material and there is a lot of enrichment happening between a simulation time of 4.0 Gyr and 7.9 Gyr. The subcluster merger can clearly be seen in the panel showing the situation at 4.0 Gyr. The emission weighted metallicity maps for model cluster 2 are presented in Fig. 6 in the two central panels. Several stripes of enriched material can be seen in the maps of model cluster 3 (see Fig. 6 lower two panels). There is also some evolution up to the end of the simulation at 7.9 Gyr.

Summarizing, our simulations enable us to derive abundance maps of the ICM. With the help of these maps we can identify the origin of highly enriched regions which have recently been observed with X-ray observations (e.g. Hayakawa et al. [2004]). Furthermore we can investigate the location and the fate of the stripped material and compare this to up to date X-ray data (e.g. Finoguenov et al. [2004]).

5. Summary and discussion

In the present paper we investigate the chemical enrichment of the ICM due to ram-pressure stripping of cluster galaxies from \( z = 1 \) to \( z = 0 \). We find that ram-pressure stripping plays a significant role in this stage of cluster evolution. In particular we investigate the efficiency, time dependence and spatial distribution of this process:

- More than 10% of the ICM originates from gas of cluster galaxies which was lost by them by ram-pressure stripping.
- Enrichment by ram-pressure stripping contributes to the overall metal enrichment of the ICM by about 10–15% within a radius of 1.3 Mpc. It is more difficult to enrich high mass clusters with high ICM densities than low mass clusters with lower ICM densities. This effect is hardly compensated by the higher efficiency of ram-pressure stripping in high mass systems.
- The total mass loss rate of all cluster galaxies depends on the cluster mass. High mass clusters can reduce the gas disks of their galaxies very quickly and enrichment of the ICM by ram-pressure stripping can take place within a few Gyr.
- Enrichment by ram-pressure stripping persists over the entire simulation time and can therefore account for some late enrichment of the ICM. This effect is more pronounced in low mass systems.
- Cluster mergers have an important impact on enrichment by ram-pressure stripping. Subcluster mergers can raise the total mass loss of all cluster galaxies significantly.
- Ram-pressure stripping can account for the total observed level of enrichment within the central 100 kpc but at larger radii other processes have to contribute to the chemical evolution of the ICM.
- Metallicity gradients are not very well suited to investigate the complex distribution of metals in the ICM. Metal maps are much more useful to investigate the present and past interactions between the ICM and the cluster galaxies.
- We find an inhomogeneous distribution of the enriched material in the ICM. This is in agreement with recent observations (e.g. Hayakawa et al. [2004]).
- In our simulations we see stripes of metal rich material which were left behind by ram-pressure affected galaxies. We note the remarkable similarity of the shape of these stripes with the plume of stripped material observed in the Virgo cluster (see Oosterloo & van Gorkom [2005]).

It seems that merger activity of the galaxy cluster has an important impact on the enrichment of the ICM due to ram-pressure stripping of cluster galaxies. Studying a larger sample of merging clusters will lead to a better understanding of this problem. In the future we plan to investigate the effect of various merger scenarios on the chemical evolution of the ICM.

In forthcoming more refined studies we will also investigate the impact of additional effects like abundance gradients in the galaxies, stripping due to Kelvin-Helmholz instabilities, shapes of bow shocks of supersonic galaxies and different galaxy evolution scenarios on the enrichment of the ICM due to ram-pressure stripping.

Acknowledgements. The authors want to thank an anonymous referee for insightful and substantial comments that greatly improved the clarity and content of this paper. This work was supported by the Austrian Science Foundation FWF under grant P15868, UniInfrastruktur 2004, Tiroler Wissenschaftsfonds, the AUSTRIAN GRID, a graduate scholarship from the University of Innsbruck, DFG grant Zi 663/6-1, the European Commission through grant number HPRICT-1999-00026 (the TRACS Program at EPCC) and by the European Commission’s Research Infrastructures activity of the Stucturing the European Research Area programme, contract number RI3-CT-2003-506079 (HPC-Europa). MM acknowledges the support of a Doktoratsstipendium of the LFU Innsbruck. EvK is supported by the FWF through grant P18416. Edmund Bertschinger and Rien van de Weygaert are acknowledged for providing their constrained random field code, Joshua Barnes and Piet Hut are acknowledged for allowing use of their treecode.
