ABSTRACT

The Magellanic Bridge (MB) is a gaseous stream that links the Large (LMC) and Small (SMC) Magellanic Clouds. Current simulations suggest that the MB forms from a recent interaction between the Clouds. In this scenario, the MB should also have an associated stellar bridge formed by stars tidally stripped from the SMC by the LMC. There are several observational evidences for these stripped stars, from the presence of intermediate age populations in the MB and carbon stars, to the recent observation of an over-density of RR Lyrae stars offset from the MB. However, spectroscopic confirmation of stripped stars in the MB remains lacking. In this paper, we use medium resolution spectra to derive the radial velocities and metallicities of stars in two fields along the MB. We show from both their chemistry and kinematics that the bulk of these stars must have been tidally stripped from the SMC. This is the first spectroscopic evidence for a dwarf galaxy being tidally stripped by a larger dwarf.

Key words: galaxies: interactions – Local Group – Magellanic Clouds.

1 INTRODUCTION

The Magellanic Bridge (MB) was discovered by Hindman, Kerr, & McGee (1963) as an H\textsc{i} gaseous structure connecting the Small (SMC) and the Large (LMC) Magellanic Clouds. Two further streams of gas – the Leading Arm and the Magellanic Stream – were later discovered by Putman et al. (1998) and Mathewson, Cleary, & Murray (1974), respectively. Initial attempts to reproduce the Magellanic System from dynamical simulations assumed multiple strong pericentric passages with the Milky Way. These were able to reproduce several features of the Magellanic System through the action of tidal stripping, ram pressure stripping, or a combination of the two (see D’Onghia & Fox 2016, for a recent compilation).

However, recent measurements of the Magellanic Cloud’s proper motions (e.g. Kallivayalil et al. 2006; Bekki & Chiba 2007) have dramatically changed our view of the Magellanic system. Their large orbital velocities make the classical assumption of multiple encounters with the Milky Way unlikely. In this context, new hypotheses have emerged. Besla et al. (2007) introduced the ‘first infall’ scenario. In this model, the Magellanic Clouds were bound to one another for a long period of time and are just now on their first infall to the Milky Way. In this picture, the MB and tail form as a result of a recent tidal interaction between the Clouds, prior to their recent accretion onto the Galaxy (Besla et al. 2012). An alternative scenario was proposed by Diaz & Bekki (2012). In this model, the LMC and the SMC have had multiple passages around the Galaxy, becoming a close binary pair only ~2 Gyr ago. The Magellanic Stream and Leading Arm form from the first interaction between the Clouds, while the latest interaction ~ 250 Myr ago formed the MB. The star formation histories of the LMC and SMC exhibit two correlated bursts of star formation at ~2 Gyr ago and ~500 Myr ago that are consistent with such close interactions between the Clouds (e.g. Noël et al. 2007, 2009).

Independently of the initial assumptions about the Magellanic Cloud’s orbits, all of the latest models favour tidal stripping as the primary mechanism for forming the Leading and trailing arms and the MB (e.g. Guglielmo, Lewis, & Bland-Hawthorn 2014). Such models

© 2017 The Authors
predict that, alongside the already observed gaseous structures, there must be companion stellar tidal debris comprised of intermediate-age and old, \( \geq 1 \) Gyr, stars. What differentiates the different models are the number of stars stripped and their origin. For example, Model 2 from Besla et al. (2012) predicts a factor to \(~5\) more stars in the MB as compared with their Model 1. In both cases, these stars originate in the SMC. By contrast, Guglielmo, Lewis, & Blund-Hawthorn (2014) predict that the MB should contain stars stripped from both the SMC and LMC.

The search for a stellar counterpart to the gaseous MB remains inconclusive. It is well known that there are young stars (\(~\lesssim100\) Myr) in this area, most likely formed in-situ (e.g. Irwin, Demers, & Kunkel 1990). In fact, Skowron et al. (2014) have shown that these young stars form a continuous stream linking both galaxies. However, intermediate-age and old stars have proven more elusive. Demers & Battinelli (1998) and Harris (2007) were unable to find any in the MB region. However, more recent studies with deeper data find an excess of stars in the regions of the color-magnitude diagram (CMD) that are expected to be populated by these stars, e.g. the red clump, at the distance of the MB. Olsen et al. (2011) found a distinct population in the LMC with a median metallicity of \([\text{M}/\text{H}] = -1.23\) dex, substantially different from the bulk of the LMC disk population. This discrepancy in the metallicity lead Olsen et al. to claim that the kinematically distinct population found in the LMC was accreted from the SMC. Nidever et al. (2011) reported a large azimuthally-symmetric metal-poor stellar population up to \(~11\) kpc from the SMC centre that was well-fitted by an exponential profile. However, they were not able to determine whether these stars constituted a bound stellar halo or extra-tidal stars. De Propris et al. (2010) found a bimodal velocity distribution of the red giant branch (RGB) stars to the east and south of the SMC centre. The second peak at larger radial velocities was interpreted as SMC stars tidally stripped from the LMC. However, this result has not been confirmed by recent studies (e.g. Dobbie et al. 2014). A stellar structure in front of the SMC main body in the eastern region at a distance of \(4\)° was reported by Nidever et al. (2013). They interpreted this as the tidally stripped stellar counterpart of the H1 gaseous bridge. As part of the MAGellanic Inter-Cloud project (MAGIC; Noël et al. 2013, 2015) we found a population with ages between 1 and 10 Gyr with a spatial distribution more spread out than the younger stars. This older population has very similar properties to the stars located at \(~2\)° from the SMC centre suggesting that they were stripped from this region.

Bagheri, Cioni, & Napiwotzki (2013) found evidence for an older population in the MB that they suggest comprised tidal debris in the region \(1^{2}0.40^\text{m} \leq \alpha \leq 4.0^\circ\) and \(-69^\circ \geq \delta \geq -77^\circ\). The radial density profiles of red clump stars in both galaxies, derived from the fourth phase of the Optical Gravitational Lensing Experiment (OGLE) by Skowron et al. (2014), shows a strong deviation. They suggest that this owes to the overlapping stellar halos of the Magellanic Clouds. Very recently, Belokurov et al. (2017) reported the existence of stellar tidal tail mapped with RR Lyrae in the Gaia DR1 database, not aligned with the gaseous MB and shifted by some \(~5\)° from the young main sequence bridge (see Fig. 1). Finally, a foreground population in the form of a distance bi-modality in the red clump distribution has been identified in the eastern SMC by Subramanian et al. (2017) with the VISTA Magellanic Clouds (VMC) survey. The authors claim that the most likely explanation for this foreground population is tidal stripping from the SMC during its most recent encounter with the LMC. Thus, most of these studies support tidal stripping of stars from the SMC. However, the nature and origin of this stellar population in the inter-Cloud region is still not fully understood.

In this paper, we set out to unequivocally test the tidal origin of the MB stellar populations older than \(~1\) Gyr. To achieve this, we present the first spectroscopic analysis of the old stellar population in the MB region. If stars in the MB are indeed tidal debris, then they should have velocities and metallicities similar to those of the SMC and/or LMC stars. By determining whether the MB stars are more SMC-like or LMC-like, we will determine whether they were stripped primarily from the SMC, the LMC, or both.

This paper is organised as follows. In Section 2, we describe the target selection, observations, and data reduction. Radial velocities and stellar metallicity determination procedures are presented in Section 3. Finally, in Section 4 we discuss the implications of our results in the context of the Magellanic Clouds’ dynamical evolution.

### Table 1. Observed stars. The full version of this table is available in the online journal and at CDS.

| 2M02250915-7202337 | 36.288123 | -72.0426988 | 15.111 | 69.1±3.6 |

2 OBSERVATIONAL DATA

We have selected two fields studied in previous MAGIC papers centred at \(\alpha = +02^\circ 4, \delta = -72^\circ 0\) (0224-7200) and \(\alpha = 02^\circ 8, \delta = -74^\circ 0\) (0224-7400), respectively. The former is located at \(6^\circ 9\) and \(14^\circ 1\) from the SMC and LMC centres, respectively; the latter at \(6^\circ 5\) and \(14^\circ 0\) from the SMC and LMC centres, respectively. The potential spectroscopic targets, selected from the expected position of the upper RGB in the CMDs, are shown in Fig. 2 (large filled circles). This sample has been extended by selecting additional potential targets from the 2MASS (Two Micron All Sky Survey; Skrutskie et al. 2006). To do that, we defined a region around the location of the objects previously selected from optical photometry (see Fig. 2). The observations were secured on the nights of the 12th and 13th November 2014 and 14th November 2016 with the AAOmega spectrograph (Saunders et al. 2004) fed by the Two Degree Field (2dF) multi-object systems installed at the prime focus of the Anglo-Australian Telescope located at Siding Spring Observatory (Australia).\(^1\) 2dF-AAOmega is a dual-beam spectrograph that allows to allocate up to 400 2"-size optical fibres within a 2° field of view. The blue arm was configured to observe blue targets located in the upper main sequence, the analysis of which will be presented in

MAGIC III: evidence of a dwarf stripping a dwarf

Figure 1. The MB region in a Hammer equal area projection. The grayscale contours represent the H\textsc{i} emission integrated over the velocity range $80 \leq V \text{[km s}^{-1}] \leq 400$, where each contour represents the H\textsc{i} column density taken from the Leiden/Argentine/Bonn – LAB – survey of Galactic H\textsc{i} (Kalberla & Haud 2015). Regions studied by different authors have been plotted in different colors: Harris (2007) in dark green; De Propris et al. (2010) in pink; and Noël et al. (2013, 2015) in blue. The region analyzed by Bagheri, Cioni, & Napierowski (2013) is denoted by dashed magenta lines. Green and orange dashed lines denote the young and RR Lyrae stars reported by Skowron et al. (2014) and Belokurov et al. (2017), respectively. The smc0053 and smc0057 fields studied by Carrera et al. (2008) in the SMC and the field LMC0356-7100 analyzed by Carrera et al. (2011) in the LMC are marked in red. The grey dots and filled black circles are stars with radial velocities above and below 100 km s\textsuperscript{-1} (the velocity cut used to separate MB stars from the Galactic foreground), respectively.

Comparing the spectrum observed in each fibre with a master sky spectrum obtained by averaging the spectra of the nearest ten fibres placed on sky positions. After sky subtraction, the spectra are then normalised by fitting a low order polynomial.

3 RADIAL VELOCITIES AND METALLICITIES

The radial velocities of the observed stars were calculated by comparing the observed spectra with a grid of synthetic spectra using the classical cross-correlation method. Details about the procedure and the grid of synthetic spectra used can be found in Carrera et al. (2017). In brief, the velocities are determined in three steps. (1) Each object spectrum is cross-correlated with a reference synthetic spectrum to obtain an initial shift for all of them. In this case, we chose: $[M/H]=-0.5$ dex; $[\alpha/Fe]=+0.0$ dex; $\xi=1.5$ km s\textsuperscript{-1}; $T_{\text{eff}}=4,500$ k; and $\log g=2.0$ dex. (2) After applying this initial shift, the observed spectrum is compared with the...

region, with radial velocities larger than 100 km s
with a velocity of 270 km s
unequivocally linked with the SMC. Except for one star
in agreement with the results obtained by
Noël et al. (2009) at a distance of
~2.5◦ and by Noël & Gallart (2007) at ~6◦ from the cen-
tre, both in the southern direction. However, the metallicity
distributions obtained in the present work are more similar
to the fields located at ~4◦ in the same direction. This is in
agreement with the stellar population with a shallow density
profile reported by Nidever et al. (2011) at a radius between
3◦ and 7:5.

The shallow extended component of the SMC described
above can be explained both by a bound stellar halo or by
extra-tidal stars. To investigate further these two scenari-
os, we have computed the velocity dispersion of the stars
with radial velocities larger than 100 km s
excluding the star with a velocity of 270 km s
There is no significant
difference between the two fields studied (Table 2). All to-
gether, these stars have an average velocity of 151.7 km s
and a dispersion of 33.3 km s
The velocity dispersion is
in good agreement with the value obtained for the SMC
σ = 26.4 km s
by Dobbie et al. (2014) but the systemic ve-
locity, (Vr) = 147.8 km s
, is slightly lower than we find here
for the inter-Cloud population.

To further explore the above, we obtained the av-
average velocity and dispersion in three metallicity bins:
[M/H] < −1.85; −1.85 < [M/H] < −1.2; and [M/H] > −1.2,
as listed in Table 2. Since the SMC has a well defined age-
metallicity relationship (e.g. Carrera et al. 2008), these three
metallicity bins can also be thought of as a proxy for three
age bins. We find that the most metal-poor stars have a
mean radial velocity very different from the other stars, and
a small dispersion of just 9.6 km s
(see Table 2). This sug-
gests that these owe to foreground contamination from Milky
Way halo stars. For the other two more metal-rich bins, we
find velocity dispersions in remarkable agreement with that
of the SMC: 26.2 km s
and 25.4 km s
, respectively (see Table 2). The excellent agreement between the velocity dis-
persion of the more metal-rich inter-Cloud stars and that
observed for stars in the SMC reinforces our hypothesis that
these inter-Cloud stars originated in the SMC.

The SMC has a stellar mass of \( M_\star \sim 4.6 \times 10^8 M_\odot \) (McConnachie 2012). Thus, we expect from abundance
matching that it would have inhabited a dark matter halo of mass \( M_{200} \sim 7 \times 10^{10} M_\odot \) before infall (e.g.
Read et al. 2017), consistent with dynamical models of the
SMC (Bekki & Stanimirović 2009). Similarly, the latest
abundance matching and dynamical mass estimates for the
LMC place it in a \( M_{200} \sim 2 \times 10^{11} M_\odot \) halo before infall (Peñarrubia et al. 2016). Treating the Clouds as point
masses moving on a pure radial orbit, and setting the tidal
radius of the SMC to \( r_t = 2.1 \) kpc (based on the similar-

4 DISCUSSION

4.1 The SMC outskirts

We have shown that stars older than ~ 1 Gyr in the MB
region, with radial velocities larger than 100 km s
are unequivocally linked with the SMC. Except for one star
with a velocity of 270 km s
, we do not find objects with
kinematics compatible with that of the LMC. This is
in agreement with the results obtained by Dobbie et al.
(2014) in the inner SMC, but contrasts with claims in
De Propris et al. (2010) and dynamical simulations from
Guglielmo, Lewis, & Bland-Hawthorn (2014). Note, how-
ever, that the stars analysed here are located almost
2° further from the SMC centre than those studied by
De Propris et al. (2010, see Fig 1).

Parisi et al. (2016) found a negative metallicity gradi-
ent in the inner SMC regions at ≤4° from its centre, and
an inversion in the outer regions between 4° and 5° towards
the Bridge. This can be interpreted as the presence of metal-
rich stars in the outer regions stripped from the inner regions
of the SMC. These results are in good agreement with the
findings of Subramanian et al. (2017) who used red clump
stars. We do not find stars more metal-rich than ~0.9 dex
and so we disfavour them coming from the inner ~2°. From
the synthetic CMD fitting technique, we conclude that the
star formation histories of the fields studied here are simi-
lar to those obtained by Noël et al. (2009) at a distance of
~2.5° and by Noël & Gallart (2007) at ~6° from the cen-
tre, both in the southern direction. However, the metallicity
distributions obtained in the present work are more similar
to the fields located at ~4° in the same direction. This is in
agreement with the stellar population with a shallow density
profile reported by Nidever et al. (2011) at a radius between
3° and 7:5.

The shallow extended component of the SMC described
above can be explained both by a bound stellar halo or by
extra-tidal stars. To investigate further these two scenari-
os, we have computed the velocity dispersion of the stars
with radial velocities larger than 100 km s
excluding the star with a velocity of 270 km s
There is no significant
difference between the two fields studied (Table 2). All to-
gether, these stars have an average velocity of 151.7 km s
and a dispersion of 33.3 km s
The velocity dispersion is
in good agreement with the value obtained for the SMC
σ = 26.4 km s
by Dobbie et al. (2014) but the systemic ve-
locity, (Vr) = 147.8 km s
, is slightly lower than we find here
for the inter-Cloud population.

To further explore the above, we obtained the av-
average velocity and dispersion in three metallicity bins:
[M/H] < −1.85; −1.85 < [M/H] < −1.2; and [M/H] > −1.2,
as listed in Table 2. Since the SMC has a well defined age-
metallicity relationship (e.g. Carrera et al. 2008), these three
metallicity bins can also be thought of as a proxy for three
age bins. We find that the most metal-poor stars have a
mean radial velocity very different from the other stars, and
a small dispersion of just 9.6 km s
(see Table 2). This sug-
gests that these owe to foreground contamination from Milky
Way halo stars. For the other two more metal-rich bins, we
find velocity dispersions in remarkable agreement with that
of the SMC: 26.2 km s
and 25.4 km s
, respectively (see Table 2). The excellent agreement between the velocity dis-
persion of the more metal-rich inter-Cloud stars and that
observed for stars in the SMC reinforces our hypothesis that
these inter-Cloud stars originated in the SMC.

The SMC has a stellar mass of \( M_\star \sim 4.6 \times 10^8 M_\odot \) (McConnachie 2012). Thus, we expect from abundance
matching that it would have inhabited a dark matter halo of mass \( M_{200} \sim 7 \times 10^{10} M_\odot \) before infall (e.g.
Read et al. 2017), consistent with dynamical models of the
SMC (Bekki & Stanimirović 2009). Similarly, the latest
abundance matching and dynamical mass estimates for the
LMC place it in a \( M_{200} \sim 2 \times 10^{11} M_\odot \) halo before infall (Peñarrubia et al. 2016). Treating the Clouds as point
masses moving on a pure radial orbit, and setting the tidal
radius of the SMC to \( r_t = 2.1 \) kpc (based on the similar-

MNRAS 000, 1–8 (2017)
ity of the stars in the inter-Cloud region with stars ∼2° from the SMC centre), we can derive the pericentric radius of the recent SMC-LMC encounter that formed the MB as: $r_p \sim r_t \left( \frac{M_{\text{LMC}}}{M_{\text{SMC}}} \right)^{1/3} \sim 1.8$ kpc (Read et al. 2006). This is in excellent agreement with recent models of tidal interactions between Clouds, where such a close encounter has been proposed to explain the LMC’s off-centre stellar bar (Besla et al. 2012). This lends further support to a tidal origin for the inter-Cloud stars.

### 4.2 Comparison with simulations

The kinematics, photometry and chemistry of stars in the MB all point to them having been tidally stripped from the SMC. In this section we perform a more direct comparison with the dynamical simulations from Diaz & Bekki (2012). In particular, we compare the location of tidally stripped stars in the MB region of the simulations with those in the locations of the fields sampled in this paper.

Although the Diaz & Bekki (2012) simulations are based on the “bound scenario”, in their favoured model the LMC and SMC suffer strong tidal interactions only recently, with two close passages ∼2 Gyr and ∼250 Myr ago. Portions of the gaseous disk of the SMC are stripped away during each of these strong encounters. In particular, the most recent one forms the gaseous bridge.

Since the gravitational field of the LMC acts in the same manner on gas and stars, a tail of stars pulled out from the SMC into the MB is expected. Diaz & Bekki (2012) assume a multi-component SMC, consisting of a spherical dark matter halo, central disc and a more extended spheroidal component. They generated three different models where the size of the spheroid was varied: “model 1” with a Plummer scale radius of 7.5 kpc; “model 2” with 5.0 kpc; and “model 3” with 2.5 kpc, respectively. This is because it is still unclear how stellar populations of different ages and metallicities are distributed within the tidal radius of the SMC.

The top panel of Fig 5 shows the predicted distribution of stars for each model. It is clear that stripped stars in all three cases are found in the MB region. However, the number of stars stripped in model 3 is much lower than for the other two models, owing to its more concentrated spheroidal population. Another interesting result is that in all cases, stripped SMC stars are captured by the LMC. This is in agreement with the peculiar stellar populations reported in the LMC by Olsen et al. (2011). In all three models, the SMC maintains an approximately spheroidal outer population after the interaction with the LMC. However, clear tidal distortions are observed towards the LMC in models 1 and 2. The position of these tails agree relatively well with location of the observed gaseous bridge (black connected dots).

On contrast, the models do not predict a significant number of tidally stripped object in the position of the recently discovered RR Lyrae bridge (gray connected dots). Although model 3 remains dense and compact, stripped stars in the MB are still present. In model 1, the edge of the spheroid almost reaches the position of our fields (open black circles). In this case, the populations there would be a mix of both bound and unbound stars. By contrast, models 2 and 3 predict mainly tidally stripped stars from the SMC at the positions of our observed fields. This is not a particularity of the Diaz & Bekki (2012) simulations. All recent models based on the latest knowledge of the Magellanic System also predict the existence of tidally stripped stars in the inter-Cloud region to a greater or lesser extent (Besla et al. 2012; Guglielmo, Lewis, & Bland-Hawthorn 2014; Belokurov et al. 2017).

These simulations also provide valuable information about the expected radial velocities of the model stars at the positions of our fields. The velocity distributions predicted...
However, model 1 predicts a continuum tail towards $-2$ only predicts a few stars between 200 and 300 km s$^{-1}$ velocity distribution of observed stars with velocities larger than 100 km s$^{-1}$ have been plotted as comparison (gray histograms).

for each model at the locations of fields 0224-7200 and 0224-7400 are shown in Fig.6. In the three models, the bulk of stars have radial velocities between $\sim$90 and $\sim$200 km s$^{-1}$. However, model 1 predicts a continuum tail towards $\sim$300 km s$^{-1}$ that is not observed in our fields. By contrast, model 2 only predicts a few stars between 200 and 300 km s$^{-1}$ while model 3 does not predict any. Our kinematic results favour models 2 and 3 over model 1. However, the spatial distributions observed in the SMC periphery favour models 1 and 2 over model 3 (and see also Diaz & Bekki 2012, for a detailed discussion). Thus, taking the spatial and velocity data together, model 2 is closest to our observations.

4.3 Dwarf/dwarf stripping

The tidal stripping of satellite galaxies is expected to be a common process (e.g. Read et al. 2006; Deason et al. 2014). Indeed, we see direct evidence for such stripping events in the Milky Way (e.g. Ibata et al. 1994), M31 (e.g. Ibata et al. 2001), and other spiral galaxies in the Local Volume (e.g. Martínez-Delgado et al. 2010, 2012). Being the most numerous type of galaxies, interactions between dwarf systems have been widely reported (e.g. López-Sánchez & Esteban 2008, 2009). In fact, stellar tidal tails have been associated with the interaction of the Magellanic analog system formed by NGC 4485 and NGC 4490 Elmegreen et al. (1998). The findings shown in this work confirm for the first time the existence of a stellar population older than 1 Gyr in the Magellanic inter-Cloud area, unequivocally related to the SMC. Moreover, these stars have a metallicity distribution similar to that of the SMC outskirts, as shown in Fig. 4. This represents the first spectroscopic evidence for dwarf-dwarf stripping in the Universe.

5 CONCLUSIONS

We have used medium resolution spectra for 514 red giant stars in the Magellanic Bridge (MB). Our key findings are as follows:

• The chemistry and kinematics for 39 of the target stars are consistent with those located $\sim$2 deg from the centre of the SMC, but inconsistent with LMC stars. We conclude, therefore, that these stars were tidally stripped from the SMC.

• We used the above to estimate the tidal radius of the SMC, finding $r_t \sim 2.1$ kpc. Using the latest estimates of the pre-infall masses of the LMC and SMC, we then estimated the closest passage between the Clouds to be $r_p \sim 1.8$ kpc. Such a close encounter has been invoked to explain the LMC’s off-centre stellar bar (Besla et al. 2012).

• We compared the spatial location and kinematics of stars in the MB region to the simulations from Diaz & Bekki (2012). We found that their “model 2” provided the best qualitative match to our data. In this model, in addition to a stellar disc and dark matter halo, the SMC has an outer spheroidal population with a Plummer scale length of 5 kpc. Models with a more concentrated spheroid produce too little tidal debris in the MB, while those with a more extended spheroid produce a tail to large radial velocities that is not observed.

• Our results represent the first spectroscopic evidence for a dwarf galaxy being tidally stripped by a larger dwarf.

ACKNOWLEDGEMENTS

We would like to thank the anonymous referee for their helpful comments that have improved this paper. We would also like to thank J. Diaz and K. Bekki for providing us with their N-body models. The research leading to these results has received funding from the European Community’s Seventh Framework Programme (FP7/2013-2016) under grant agreement number 312430 (OPTICON). BCC acknowledges the support of the Australian Research Council through Discovery project DP150100862. This work was supported by the Spanish Ministry of Economy through grant AYA2014-56795P.
