Abstract

We study the problem of estimating the common mean $\mu$ of $n$ independent symmetric random variables with different and unknown standard deviations $\sigma_1 \leq \sigma_2 \leq \cdots \leq \sigma_n$. We show that, under some mild regularity assumptions on the distribution, there is a fully adaptive estimator $\hat{\mu}$ such that it is invariant to permutations of the elements of the sample and satisfies that, up to logarithmic factors, with high probability,

$$|\hat{\mu} - \mu| \lesssim \min \left\{ \sigma_{m^*}, \frac{\sqrt{n}}{\sum_{i=m^*}^{n} \sigma_i^{-1}} \right\},$$

where the index $m^* \lesssim \sqrt{n}$ satisfies $m^* \approx \sqrt{\sigma_{m^*} \sum_{i=m^*}^{n} \sigma_i^{-1}}$.

1 Introduction

In this note we study the problem of estimating the common mean $\mu \in \mathbb{R}$ of $n$ independent real random variables $X_1, \ldots, X_n$. These random variables do

not need to be identically distributed. Moreover, the variances of the $X_i$ may greatly vary and therefore the information each observation carries about the mean may be different. For the sake of this introductory discussion, assume that the $X_i$ all have normal distribution so that $X_i \sim \mathcal{N}(\mu, \sigma_i^2)$ for some $0 < \sigma_1 \leq \cdots \leq \sigma_n$.

If the values of the standard deviations $\sigma_i$ were known, then one could choose the maximum likelihood estimator

$$\hat{\mu} = \frac{\sum_{i=1}^{n} \frac{X_i}{\sigma_i^2}}{\sum_{i=1}^{n} \frac{1}{\sigma_i^2}},$$

leading to an expected error $\mathbb{E} |\hat{\mu} - \mu| \leq \left( \sum_{i=1}^{n} \sigma_i^{-2} \right)^{-1/2}$. The general study of such estimators goes back to \cite{Ibragimov:Hasminskii1981} Chapter 3, Section 4) where the estimation of a single parameter based on independent but non-identically distributed observations is studied. However, this idealistic estimator assumes that the standard deviation of each sample point is known to the statistician.

In this note we consider the situation where nothing is known about the values of the $\sigma_i$ (or their assignments to the data points). In particular, we focus on the estimators invariant to permutations of the elements of the sample. Naturally, one may always compute the sample mean $(1/n)\sum_{i=1}^{n} X_i$. However, the sample mean has an error of the order of $(1/n)\left( \sum_{i=1}^{n} \sigma_i^{-2} \right)^{1/2}$ whose performance deteriorates even if a single data point has a large variance.

For symmetric distributions like the normal distribution, another – and more robust – natural estimator of the mean is the sample median. One of the contributions of this note is to provide new non-asymptotic performance guarantees for the sample median. In particular, we show that under some mild assumptions the error of the sample median is bounded, with high probability, by

$$\frac{c \sqrt{n \log n}}{\sum_{i=1}^{n} \sqrt{\sigma_i^{-1}}}$$

for some constant $c$ (see Proposition\[1\] for the rigorous statement).

As simple as the sample median is, it has the disadvantage that it does not take advantage of the presence of data points with very small variance. Indeed, the performance of the sample median is essentially insensitive to the approximately $\sqrt{n}$ smallest variances. At the same time, the presence of data with very small variances makes the problem much easier. A simple way to exploit such situations is in using the so-called modal interval estimator introduced by \cite{Chernoff1964} for estimating the mode of a density function. The modal interval estimator looks for the most populated interval of a certain length $s > 0$ and outputs its mid-point. The main challenge in applying this method in our setting is that without any knowledge of the variances $\sigma_1, \sigma_2, \ldots$ it is a hard to establish a good value of $s$ a priori. In Proposition\[2\] below we
establish a simple sufficient condition for the length $s$ that guarantees that the modal interval contains the mean $\mu$. Roughly speaking, this condition guarantees that random fluctuations of the data far from the mean cannot produce an interval of length $s$ that has more points than the expected number of points in the interval of same length centered at the mean $\mu$. We call such “good” values of $s$ admissible. Admissibility of an interval length depends, in a complex way, on the entire sequence $\sigma_1, \ldots, \sigma_n$. Ideally, one would like to use the modal interval estimator with the smallest possible admissible interval length. The main contribution of this note is a fully adaptive estimator that essentially achieves this goal. More precisely, without any previous knowledge of the $\sigma_i$, we show that one can construct a completely data-driven estimator that has a performance at least as good (up to constant factors in the error) as the best of the sample median and the modal interval estimator with the smallest admissible interval length.

In the remainder of this introduction we discuss previous related work. In Section 2 the analysis of the sample median is presented. We also show that an appropriately chosen median interval is a valid empirical confidence interval. This is important in the construction of the adaptive estimator. The modal interval estimator is analyzed in Section 3. The fully adaptive estimator is described in Section 4 and its performance guarantees are established in Theorem 1. In Section 5 we take a closer look at some concrete examples and compare our performance bounds with those of previous work.

Related work

For some classical references on the maximum likelihood estimator in our setup we refer to the work of Ibragimov and Has’minskii (1976) and Beran (1982). The sample median has been analyzed in the literature in our setup. For example, Mizera and Wellner (1998) provide necessary and sufficient conditions for the consistency of the sample median for triangular arrays of independent, not identically distributed random variables (in a more general setting than ours). The role of the sum of the reciprocals of the standard deviations as in (1.1) appears in early work. In particular, the result of Nevzorov (1984, Theorem 2) can be used to provide rates of convergence of the sample median to the normal law for non-identically distributed Gaussian data that involves $\sum_{i=1}^{n} \sigma_i^{-1}$. The work of Gordon, Litvak, Schütte and Werner (2006, Theorem 7) uses this quantity in the context of the moments of order statistics for non-identically distributed random variables. Moreover, the work of Xia (2019, Corollary 6) makes direct connections between the sum of reciprocals and the performance of the sample median, see Section 5 for a detailed comparison. The same quantity appears in the analysis of the iterative trimming algorithm of Liang and Yuan (2020, Remark following Theorem 1). Importantly, in the context of the mean estimation problem, some of the above-mentioned results provide performance guarantees when the value of $\sum_{i=1}^{n} \sigma_i^{-1}$ is large, whereas our bounds provide sharp guarantees for the entire
range of values of the sum of reciprocals of the standard deviations.

The most related papers are (Chierichetti, Dasgupta, Kumar and Lattanzi; 2014), (Pensia, Jog and Loh; 2019), and (Liang and Yuan; 2020). For example, Chierichetti et al. (2014) construct an estimator whose error is bounded, with high probability, by \( \widetilde{O}(\sqrt{n\sigma \log n}) \), where \( \widetilde{O}(\cdot) \) suppresses multiplicative poly-logarithmic factors. The hybrid estimator of Pensia et al. (2019, Proposition 5) uses a combination of the shortest gap with the median estimators, quite similar to our estimator. However, in contrast to these previous results, the estimator proposed here is fully adaptive and thus requires no tuning parameters. Our estimator also compares favourably with the iterative trimming algorithm of Liang and Yuan (2020), which does not cover the entire range of the values of \( \sigma_1, \ldots, \sigma_n \) and depends on some tuning parameters and the initialization. Section 5 includes extensive comparisons with these papers. In particular, we show that, up to logarithmic factors, our bounds are never worse than the previous (non-adaptive) bounds.

Notation

In what follows, we denote \( a \wedge b = \min\{a, b\} \) and \( a \vee b = \max\{a, b\} \). Given \( X_1, \ldots, X_n \) let \( X_{(1)}, \ldots, X_{(n)} \) denote the non-decreasing rearrangement of its elements. The value \( X_{(i)} \) is usually referred to as the \( i \)-th order statistic. In what follows, \( a \lesssim b \) and \( b \gtrsim a \) denote the existence of a numerical constant \( c \) such that \( a \leq cb \). The numerical constants are denoted by \( c, c_1, c_2, \ldots > 0 \). Their values may change from line to line. We also use the standard \( O(\cdot) \) notation as well as its version \( \widetilde{O}(\cdot) \) that suppresses multiplicative poly-logarithmic factors. Finally, let \( [n] \) denote the set \{1, \ldots, n\}.

2 Analysis of the \( \alpha \)-median interval

When the distribution of each random variable \( X_i \) is symmetric about the mean \( \mu \), the empirical median is a natural estimator of the mean. In this section we present an analysis of the empirical median. We assume the following regularity conditions.

**Assumption A.** Let \( X_1, \ldots, X_n \) be independent random variables and let \( 0 < \sigma_1 \leq \cdots \leq \sigma_n \). We assume that

(i) \( \mathbb{E}X_i = \mu \) for all \( i \in [n] \);

(ii) Symmetry: for each \( i \in [n] \), \( X_i - \mu \) and \( \mu - X_i \) have the same distribution;

(iii) Tail assumption: for some constant \( \beta > 0 \), we have that for any \( t > 0 \),

\[
\mathbb{P}\{|(X_i - \mu)/\sigma_i| \geq t\} \leq \exp(-\beta t) .
\]  

(2.1)

A canonical example satisfying Assumption [A] is when \( X_i \sim \mathcal{N}(\mu, \sigma_i^2) \). In this case one may choose \( \beta = \sqrt{\frac{2}{\pi}} \). Note that we do not need to assume that
the \((X_i - \mu)/\sigma_i\) are identically distributed. It suffices that they are independent, symmetric, and satisfy the tail assumption (2.1). Note also that condition (iii) implies that \(P(|(X_i - \mu)/\sigma_i| < t)\) is lower bounded by \(\beta t/2\) for \(t \leq 2/\beta\). In particular, if \(X_i\) has an absolute continuous distribution, this assumption implies that the density of \((X_i - \mu)/\sigma_i\) is bounded away from zero near zero.

For reasons that will become apparent later, we consider not only the empirical median as a point estimator but also the so-called median interval, defined as the interval whose endpoints are \(X_{(n/2-k)}\) and \(X_{(n/2+k)}\) for an appropriately chosen value of \(k\). This will allow us to obtain an empirical confidence interval that is essential for our adaptive procedure.

To define the median interval, assume, for simplicity, that \(X_i\) has an absolute continuous distribution, this assumption implies that the density of \((X_i - \mu)/\sigma_i\) is bounded away from zero near zero.

We fix \(\alpha \in (0, \sqrt{n}/2)\) such that \(\alpha \sqrt{n}\) is an integer. Consider the random interval

\[
I_\alpha = [X_{\lfloor n/2-\alpha \sqrt{n}\rfloor}, X_{\lceil n/2+\alpha \sqrt{n}\rceil}] .
\] (2.2)

We refer to \(I_\alpha\) as the \(\alpha\)-median interval. Our first result provides two key properties of the median interval: if \(\alpha\) is proportional to \(\sqrt{\log(1/\delta)}\), the interval \(I_\alpha\) contains the mean \(\mu\) with probability at least \(1 - \delta\). Moreover, we provide an upper bound for the length of \(I_\alpha\) in terms of the sum of the reciprocals of the standard deviations.

**Proposition 1.** Let Assumption \(\Box\) be satisfied. Fix \(\delta \in (0, 1)\) such that \(128\log 8 \leq n\) and set \(\alpha = \sqrt{2\log 8}\). The median interval \(I_\alpha\) satisfies, with probability at least \(1 - \delta\), that \(\mu \in I_\alpha\) and

\[
|I_\alpha| \leq 8e\sqrt{2} \left(\frac{3}{\delta} \vee \log(n+1)\right) \beta^{-1} \max_{1 \leq j \leq 8\alpha \sqrt{n}} \frac{8\alpha \sqrt{n} + 1 - j}{\sum_{i=j}^{8\alpha \sqrt{n}} \sigma_i^{-1}} .
\]

Note that by ignoring constant factors, Proposition \(\Box\) implies

\[
|I_\alpha| \lesssim \beta^{-1} \log \left(\frac{n}{\delta}\right) \frac{\alpha \sqrt{n}}{\sum_{i=8\alpha \sqrt{n}}^{\infty} \sigma_i^{-1}} .
\] (2.3)

The key to the proof of Proposition \(\Box\) is following rearrangement inequality due to [Gordon et al. (2006), Theorem 7]. Let \(|X|_{(1)}, \ldots, |X|_{(n)}\) denote the non-decreasing rearrangement of \(|X_1|, \ldots, |X_n|\).

**Lemma 1.** Let \(X_1, \ldots, X_n\) be independent random variables such that for \(0 < \sigma_1 \leq \cdots \leq \sigma_n\) and \(\beta > 0\), for all \(t > 0\), \(P(|X_i/\sigma_i| \geq t) \leq \exp(-\beta t)\). Then for all \(p \geq 1\) and \(1 \leq k \leq n\),

\[
\left(\mathbb{E}(|X|_k)^p\right)^{\frac{1}{p}} \leq 4\sqrt{2} \max_p \log(k+1) \beta^{-1} \max_{1 \leq j \leq k} \frac{k+1-j}{\sum_{i=j}^{n} \sigma_i^{-1}} .
\]
Proof of Proposition 1. First, we show that $\mu \in I_\alpha$. Without loss of generality, we may assume that $\mu = 0$ for the rest of the proof. Let $\varepsilon_1, \ldots, \varepsilon_n$ be independent Rademacher random variables. Since the distribution of each $X_i$ is assumed to be symmetric, $(\varepsilon_1 X_1, \ldots, \varepsilon_n X_n)$ has the same distribution as $(X_1, \ldots, X_n)$. Conditioning on the $X_1, \ldots, X_n$, we have, by Hoeffding’s inequality,

$$
P(\mu \notin I_\alpha) = P\left(\sum_{i=1}^{n} \varepsilon_i > a \sqrt{n}\right) \leq 2 \exp\left(-\frac{a^2}{2}\right).
$$

We denote the event that $\mu \in I_\alpha$ by $E_1$ and proceed with the bound on the length of the interval $|I_\alpha|$. Fix $k \leq n$ and consider $|X|_{(1)}, \ldots, |X|_{(k)}$ — these are the absolute values of the $k$ observations closest to $\mu = 0$. Note that, depending on the realizations of the random signs $\varepsilon_i$, the corresponding values $\varepsilon |X|_i$ may be on either side of $\mu = 0$. Let $E_2$ be the event that there are more than $k/4$ of these $k$ observations on both sides of $\mu$. By a simple binomial estimate,

$$
P(E_2) \geq 1 - 2 \exp\left(-\frac{k}{8}\right).
$$

Consider the event $E_1 \cap E_2$ and choose $k = 8\alpha \sqrt{n}$ so that at least $2\alpha \sqrt{n} + 1$ of these closest observations are on both sides of $\mu$. On this event since $I_\alpha$ contains $\mu = 0$ and exactly $2\alpha \sqrt{n} + 1$ observations, both $|X|_{(n/2 - \alpha \sqrt{n})} \leq |X|_{(8\alpha \sqrt{n})}$ and $|X|_{(n/2 + \alpha \sqrt{n})} \leq |X|_{(8\alpha \sqrt{n})}$ hold. Therefore, on the event $E_1 \cap E_2$,

$$
|I_\alpha| \leq 2|X|_{(8\alpha \sqrt{n})}. \tag{2.4}
$$

Finally, we use Lemma 1 to control $|X|_{(8\alpha \sqrt{n})}$. By Markov’s inequality and Lemma 1, we have

$$
P\left(|X|_{(8\alpha \sqrt{n})} \geq t\right) \leq \frac{E|X|^p_{(8\alpha \sqrt{n})}}{t^p} \leq t^{-p} \left(4\sqrt{2} \max\{p, \log(8\alpha \sqrt{n} + 1)\} \beta^{-1} \max_{1 \leq j \leq 8\alpha \sqrt{n}} \frac{k+1-j}{\sum_{i=j}^{n} \sigma_i^{-1}}\right)^p.
$$

Denote $\gamma = 4\sqrt{2} \beta^{-1} \max_{1 \leq j \leq 8\alpha \sqrt{n}} \frac{k+1-j}{\sum_{i=j}^{n} \sigma_i^{-1}}$. Provided that $\gamma \geq \log(8\alpha \sqrt{n} + 1)$, we may fix $p = \frac{t}{\gamma^p}$ and get

$$
P\left(|X|_{(8\alpha \sqrt{n})} \geq t\right) \leq \exp\left(-\frac{t}{\gamma^p}\right).
$$

Fixing $t = (\log \frac{3}{\delta} \sqrt{\log(8\alpha \sqrt{n} + 1)}) \epsilon \gamma$ we have that, with probability at least $1 - \delta/3$,

$$
|X|_{(8\alpha \sqrt{n})} \leq 4\sqrt{2} \left(\log \frac{3}{\delta} \sqrt{\log(8\alpha \sqrt{n} + 1)}\right) \beta^{-1} \max_{1 \leq j \leq 8\alpha \sqrt{n}} \frac{k+1-j}{\sum_{i=j}^{n} \sigma_i^{-1}}.
$$
Denote this event by $E_3$.

Choosing $\alpha = \sqrt{2 \log \frac{2}{\delta}}$ we have $\mathbb{P}(E_1) \geq 1 - \delta/3$. Since $\alpha \sqrt{n} \geq 2\alpha^2$, we have $\mathbb{P}(E_2) \geq 1 - 2\exp\left(-\alpha \sqrt{n}\right) \geq 1 - 2\exp\left(-4\log \frac{2}{\delta}\right) \geq 1 - \delta/3$. Therefore, we have by the union bound, that $E_1 \cap E_2 \cap E_3$ is of probability at least $1 - \delta$. On this event due to (2.4) we have

$$|I_\alpha| \leq 8e\sqrt{2\left(\log \frac{3}{\delta} + \log(8\alpha \sqrt{n} + 1)\right)} \beta^{-1} \max_{1 \leq j \leq 8\sqrt{2\log \frac{2}{\delta}}} \frac{k + 1 - j}{\sum_{i=j}^{n} \sigma_i^{-1}}.$$ 

The claim follows by observing that $k = 8\alpha \sqrt{n} \leq n$ is equivalent to $128\log \frac{2}{\delta} \leq n$.

**Corollary 1.** Under the assumptions of Proposition 1, the median $X_{(n/2)}$ satisfies, with probability at least $1 - \delta$,

$$|X_{(n/2)} - \mu| \leq 8e\sqrt{2\left(\log \frac{3}{\delta} + \log(n + 1)\right)} \beta^{-1} \max_{1 \leq j \leq 8\sqrt{2\log \frac{2}{\delta}}} \frac{8\sqrt{2\log \frac{2}{\delta}} + 1 - j}{\sum_{i=j}^{n} \sigma_i^{-1}}.$$ 

**Proof.** Indeed, with probability at least $1 - \delta$, both $\mu$ and $X_{(n/2)}$ belong to $I_\alpha$ for $\alpha$ as in Proposition 1, and therefore, $|X_{(n/2)} - \mu| \leq |I_\alpha|$.

### 3 Modal interval estimator

The second component of our adaptive estimator is the simple and natural estimator that looks for an interval of a given length containing the maximum number of data points. This is the so-called modal interval estimator introduced by Chernoff (1964) for estimating the mode of a density function. Pensia et al. (2019) also analyze this estimator though their bounds have some limitations for our purposes. We make a detailed comparison in Section 5 below.

In this section we work under the following assumptions.

**Assumption B.** Let $X_1, \ldots, X_n$ be independent random variables such that $X_i$ has density $(1/\sigma_i)\phi((x - \mu)/\sigma_i)$ where $\phi$ is some fixed density function, $\mu$ is a location parameter and $\sigma_1 \leq \cdots \leq \sigma_n$ are positive scale parameters. Assume that

(i) $\int x\phi(x)dx = 0$. This implies that $\mathbb{E}X_i = \mu$ for all $i \in \{n\}$.

(ii) $\int x^2\phi(x)dx = 1$. This implies that $\text{Var}(X_i) = \sigma_i^2$ for all $i \in \{n\}$.

(iii) Symmetry: $\phi(-x) = \phi(x)$ for all $x \in \mathbb{R}$.

(iv) Unimodality: $\phi(x)$ is non-increasing for $x > 0$ and non-decreasing for $x < 0$.

An important example satisfying Assumption [B] is the Gaussian case, that is, when $\phi(x) = (1/\sqrt{2\pi})e^{-x^2/2}$. However, in general, $\phi$ may have a heavy tail.
as long as the second moment exists. We also do not need to assume that \( \phi \) is bounded. Introduce the notation

\[
\Phi(t) = \int_{-t}^{t} \phi(x)dx.
\]

For \( s > 0 \), denote the interval \( A_s(x) = [x - s, x + s] \). Let

\[
D_s(x) = \sum_{i=1}^{n} 1_{X_i \in A_s(x)}
\]

be the number of points in the interval \( A_s(x) \). Denoting \( q_i(s) = P\{X_i \in A_s(\mu)\} = \Phi(s/\sigma_i) \), we have

\[
E D_s(\mu) = \sum_{i=1}^{n} q_i(s).
\]

Define the \textit{modal interval estimator} which returns the center of the densest interval of length \( 2s \). That is,

\[
\hat{\mu}_{n,s} \in \arg\max_{x \in \mathbb{R}} D_s(x).
\] (3.1)

For the modal interval estimator to work (in the sense that it contains the common mean \( \mu \)), the length \( s \) has to satisfy certain conditions. Such a sufficient condition is formulated in the following definition that intuitively captures the fact that the densest interval should contain \( \mu \), even after accounting for random fluctuations. In Proposition 2 below we prove the condition of admissibility specified here is indeed sufficient.

**Definition 1.** Fix the confidence \( \delta > 0 \) and the interval length \( s > 0 \). Define

\[
m_s = \max\{m \in \{n\} : \sigma_m \leq s\}.
\]

We say that the length \( s \) is \textit{admissible} if

\[
m_s \geq \kappa \left( \sqrt{E D_s(\mu) \log \frac{2n}{\delta} + \log \frac{2n}{\delta}} \right),
\]

where \( \kappa > 0 \) is a numerical constant. Finally, we set

\[
\overline{\delta}(\delta) = \inf\{s > 0 : s \text{ is admissible}\}.
\] (3.2)

**Remark.** The value of the constant \( \kappa > 0 \) depends on a universal constant appearing in Lemma 2 below. While it is possible to extract a specific value, it is somewhat tedious and not crucial for our arguments, so we prefer to keep it unspecified. All results below hold for all values of \( \kappa \geq \kappa_0 \) for some constant \( \kappa_0 \). Changing the value only effects the constants in the results below.
Remark. Observe that if the density is bounded, that is, if \( \phi(0) \) is finite, we have \( q_i(s) \leq \min\{1, 2\phi(0)/\sigma_i\} \). Therefore, adjusting the constant \( \kappa \), we may replace the admissibility criterion by the condition

\[
m_s \geq \kappa \left( \sqrt{\sum_{i=1}^{n} \min\left\{ 1, 2\phi(0)\frac{s}{\sigma_i} \right\}} \log \frac{2n}{\delta} + \log \frac{2n}{\delta} \right),
\]

Roughly speaking, whenever \( \phi(0) \) is finite one may think that \( s(\delta) \) is approximately equal to \( \sigma_{m^*} \), where \( m^* \) is the smallest integer satisfying

\[
m^* \geq \sqrt{\frac{n}{\sum_{i=m^*}^{n} \frac{1}{\sigma_i}}} \log \frac{n}{\delta}.
\]

The main result of this section is the following bound.

**Proposition 2.** Let Assumption [B] be satisfied. Fix \( \delta \in (0, 1) \). Then, with probability at least \( 1 - \delta \), simultaneously for all admissible \( s > 0 \), it holds that

\[
\left| \hat{\mu}_{n,s} - \mu \right| \leq 4s.
\]

**Proof.** We start by showing a simple lower bound for \( \Phi(1) = 2 \int_0^1 \phi(x)dx \). Fix any \( t \geq 1 \) and observe that by property (iv) in Assumption [B] we have \( t\Phi(1) \geq \Phi(t) \). At the same time, by Chebyshev’s inequality and property (ii) we have \( \Phi(t) > (1 - 1/t^2) \). Therefore,

\[
\Phi(1) \geq \sup_{t \geq 1} \frac{1}{t} \left( 1 - \frac{1}{t^2} \right) = \frac{2}{3\sqrt{3}}. \tag{3.3}
\]

As the estimator is translation invariant, we may assume, without loss of generality, that \( \mu = 0 \). We show that, on the one hand, with probability at least \( 1 - \delta/2 \), simultaneously for all admissible \( s \),

\[
\max_{x \in \mathbb{R}} D_s(x) \geq m_s \frac{3\Phi(1)}{4} + \sum_{i > m_s} q_i(s), \tag{3.4}
\]

and, on the other hand, with probability at least \( 1 - \delta/2 \),

\[
\max_{x \in \mathbb{R}: |x| \geq 4s} D_s(x) < m_s \frac{3\Phi(1)}{4} + \sum_{i > m_s} q_i(s). \tag{3.5}
\]

These two properties together imply the proposition. First, we show (3.4). Note that for \( i \leq m_s \) we have \( \sigma_i \leq s \) and \( q_i(s) = \mathbb{P}[X_i \in A_s(0)] \geq \Phi(1) \), and therefore,

\[
\mathbb{E}D_s(0) = \sum_{i=1}^{n} q_i(s) \geq m_s \Phi(1) + \sum_{i > m_s} q_i(s). \tag{3.6}
\]
Observe that, since $s$ is admissible, we have

$$m_s \Phi(1) \geq \Phi(1) \left( \kappa \sqrt{\mathbb{E} D_s(0) \log \frac{2n}{\delta}} + \kappa \log \frac{2n}{\delta} \right) \geq \frac{2}{3\sqrt{3}} \left( \kappa \sqrt{\mathbb{E} D_s(0) \log \frac{2n}{\delta}} + \kappa \log \frac{2n}{\delta} \right). \quad (3.7)$$

Denote $\kappa' = \frac{2}{3\sqrt{3}} \kappa$. Using (3.7), we have

$$\mathbb{P} \left\{ \exists s > 0 : s \text{ is admissible}, \max_{x \in \mathbb{R}} D_s(x) \leq m_s \frac{3\Phi(1)}{4} + \sum_{i > m_s} q_i \right\} \leq \mathbb{P} \left\{ \exists s > 0 : s \text{ is admissible}, D_s(0) \leq m_s \frac{3\Phi(1)}{4} + \sum_{i > m_s} q_i \right\} \leq \mathbb{P} \left\{ \exists s > 0 : s \text{ is admissible}, D_s(0) \leq \mathbb{E} D_s(0) - m_s \frac{\Phi(1)}{4} \right\} \leq \mathbb{P} \left\{ \exists s > 0 : s \text{ is admissible}, \mathbb{E} D_s(0) - D_s(0) \geq \kappa' \frac{\sqrt{\mathbb{E} D_s(0) \log \frac{2n}{\delta}} + \kappa' \log \frac{2n}{\delta}}{4} \right\}.$$ 

By Lemma 2 in Appendix A, since the vc dimension of the family intervals in $\mathbb{R}$ equals 2, one may tune the value of $\kappa'$ such that the last probability is bounded by $\frac{\delta}{2}$.

We are now ready to analyze (3.5) for which it is enough to show that

$$\mathbb{P} \left\{ \exists s \geq 0 \text{ and } |x| \geq (1 + \sqrt{2/\Phi(1)}) s : s \text{ is admissible and } D_s(x) > m_s \frac{3\Phi(1)}{4} + \sum_{i > m_s} q_i \right\} \leq \frac{\delta}{2}. \quad (3.8)$$

Observe that by (3.3) we have $1 + \sqrt{2/\Phi(1)} \leq 4$. Given $x$ such that $|x| > 4s > (1 + \sqrt{2/\Phi(1)}) s$, using the properties of the density $\phi$ together with $s \geq \sigma_{m_s}$ and Chebyshev’s inequality, we have

$$\mathbb{E} D_s(x) = \sum_{i \leq m_s} \mathbb{P}[X_i \in A_s(x)] + \sum_{i > m_s} \mathbb{P}[X_i \in A_s(x)] \leq \sum_{i \leq m_s} \mathbb{P}[|X_i| \geq \sqrt{2/\Phi(1)} s] + \sum_{i > m_s} \mathbb{P}[X_i \in A_s(x)] \leq m_s \frac{\Phi(1)}{2} + \sum_{i > m_s} q_i.$$
Using this inequality together with (3.7) and recalling that \( \kappa' = \frac{2}{3\sqrt{3}} \kappa \), we have

\[
\begin{align*}
&\mathbb{P}\left\{ \exists s \geq 0 \text{ and } |x| \geq 4s : s \text{ is admissible, } D_s(x) > m_s \frac{3\Phi(1)}{4} + \sum_{i>m_s} q_i \right\} \\
&\leq \mathbb{P}\left\{ \exists s \geq 0 \text{ and } |x| \geq 4s : s \text{ is admissible, } D_s(x) > \mathbb{E}D_s(x) + m_s \frac{\Phi(1)}{4} \right\} \\
&\leq \mathbb{P}\left\{ \exists s \geq 0 \text{ and } |x| \geq 4s : s \text{ is admissible, } D_s(x) > \mathbb{E}D_s(x) + \kappa' \frac{2n}{\delta} \log \frac{2n}{\delta} \right\}.
\end{align*}
\]

Using \( \mathbb{E}D_s(x) \leq \mathbb{E}D_s(0) \), the last line is bounded by

\[
\begin{align*}
&\mathbb{P}\left\{ \exists s \geq 0 \text{ and } |x| \geq 4s : s \text{ is admissible, } \\
&D_s(x) > \mathbb{E}D_s(x) + \frac{\kappa'}{4} \mathbb{E}D_s(0) \log \frac{2n}{\delta} + \frac{\kappa' \log 2}{4} \right\}.
\end{align*}
\]

Finally, the last expression and Lemma 2 which holds simultaneously for all \( x \) and \( s \), implies (3.8) by adjusting the constant \( \kappa \) (and thus \( \kappa' \)). The proof is complete.

4 An adaptive estimator: combining the median and the modal Interval

Proposition 2 shows that, as long as \( s \) is an admissible value, the modal interval estimator has an error bounded by \( 4s \). Hence, to optimize the bound, one should choose \( s \) to be the smallest possible admissible value, that is, \( \overline{s}(\delta) \) introduced in Definition 1. However, the value of \( \overline{s}(\delta) \) depends on the values \( \sigma_1, \ldots, \sigma_n \) and therefore one doesn’t have access to \( \overline{s}(\delta) \) unless the standard deviations are known (up to a permutation), a typically unrealistic requirement. In this section we introduce an adaptive estimator that is able to find an approximate value of \( \overline{s}(\delta) \) based only on the available data \( X_1, \ldots, X_n \). Furthermore, the adaptive estimator combines the \( \alpha \)-median interval estimator with the modal interval estimator and achieves an error that is at least as good as the best of the median and the optimal modal interval estimator, up to a constant factor.

The key to making the estimator adaptive is an empirical criterion, based on which one can reject values of \( s \) that are not admissible. Once one has such a criterion, standard techniques of adaptive estimation may be applied (such as Lepski’s method (Lepski, 1992)).
Fix $\delta > 0$ and $s > 0$. Let $\eta, \xi > 0$ be numerical constants specified in the proof. Based on $X_1, \ldots, X_n$ let $\hat{\mu}_{n,s}$ be any maximizer of $D_s(x)$ defined by (3.1).

- We ACCEPT the interval $A_s(\hat{\mu}_{n,s})$ if $D_s(\hat{\mu}_{n,s}) \geq \xi \log \frac{2n}{\delta}$ and

  $$\max_{x \in \mathbb{R}, |x - \hat{\mu}_{n,s}| \geq 8s} D_s(x) \leq D_s(\hat{\mu}_{n,s}) - \eta \left( \sqrt{D_s(\hat{\mu}_{n,s}) \log \frac{2n}{\delta}} + \log \frac{2n}{\delta} \right).$$

- Otherwise, we REJECT this interval.

**Remark.** Since we only consider $D_s(\hat{\mu}_{n,s}) \geq \xi \log \frac{2n}{\delta}$ we may instead consider a criterion of the form

  $$\max_{x \in \mathbb{R}, |x - \hat{\mu}_{n,s}| \geq 8s} D_s(x) \leq D_s(\hat{\mu}_{n,s}) - \eta' \sqrt{D_s(\hat{\mu}_{n,s}) \log \frac{2n}{\delta}},$$

for some $\eta' > 0$. However, the choice above makes the proof more transparent.

This criterion satisfies the following relation.

**Proposition 3.** With probability at least $1 - \delta$, simultaneously for all $s > 0$, no interval with $|\hat{\mu}_{n,s} - \mu| > 8s$ is accepted and every admissible interval is accepted.

**Proof.** Recall that, without the loss of generality, we set $\mu = 0$. From now on we work on the event $E_1$ where the inequalities of Lemma 2 hold. We begin by proving that any admissible $s > 0$ is accepted with high probability. We have shown in the proof of Proposition 2 that one the event $E_1$, for all admissible values of $s$,

$$|\hat{\mu}_{n,s}| \leq 4s.$$  

Therefore, on this event any $x \in \mathbb{R}$ such that $|x - \hat{\mu}_{n,s}| \geq 8s$ satisfies $|x| \geq 4s$. Also, by the argument in the proof of Proposition 2 and Lemma 2 we have for all $|x| \geq 4s$,

$$D_s(x) \leq m_s \frac{\Phi(1)}{2} + \sum_{i > m_s} q_i + c_1 \left( \sqrt{\mathbb{E}D_s(x) \log \frac{2n}{\delta}} + \log \frac{2n}{\delta} \right)$$

$$\leq m_s \frac{\Phi(1)}{2} + \sum_{i > m_s} q_i + c_1 \left( \sqrt{\mathbb{E}D_s(0) \log \frac{2n}{\delta}} + \log \frac{2n}{\delta} \right),$$  

where $c_1 > 0$ is a numerical constant.

Observe that the function $y \mapsto y - \eta \sqrt{y \log \frac{2n}{\delta}}$ is increasing whenever $y > \eta^2 \log \frac{2n}{\delta} / 4$. Thus, $D_s(0) \geq \eta^2 \log \frac{2n}{\delta} / 4$ implies

$$D_s(\hat{\mu}_{n,s}) - \eta \left( \sqrt{D_s(\hat{\mu}_{n,s}) \log \frac{2n}{\delta}} + \log \frac{2n}{\delta} \right) \geq D_s(0) - \eta \left( \sqrt{D_s(0) \log \frac{2n}{\delta}} + \log \frac{2n}{\delta} \right).$$  

(4.2)
Observe also that the line (A.7) in the proof of Lemma 2 implies that on the event $E_1$ it holds simultaneously for all $x$ that

$$D_s(x) \leq 2\mathbb{E}D_s(x) + c_2 \log \frac{2n}{\delta}, \quad (4.3)$$

where $c_2 > 0$ is a numerical constant. By (3.4), on the same event, $D_s(0) \geq m_s \Phi(1) + \sum_{i > m_s} q_i(s)$, and therefore, using the admissibility of $s$, the inequality (4.2) implies

$$D_s(\hat{\mu}_{n,s}) - \%\left(\sqrt{D_s(\bar{\mu}_{n,s}) \log \frac{2n}{\delta} + \log \frac{2n}{\delta}}\right) \geq m_s \Phi(1) + \sum_{i > m_s} q_i(s) - \%\left(\sqrt{D_s(0) \log \frac{2n}{\delta} + \log \frac{2n}{\delta}}\right)$$

where $\kappa'$ is defined in the proof of Proposition 2 and in the last line we used $\sqrt{a + b} \leq \sqrt{a} + \sqrt{b}$ for $a, b \geq 0$. Comparing this with (4.1) and choosing a sufficiently large value of $\kappa$ in Definition 1, we prove that admissible intervals are accepted with high probability. It is only left to check that $D_s(\bar{\mu}_{n,s}) \geq \xi \log \frac{2n}{\delta}$ and that, given that the constant $\xi$ is properly adjusted, our additional acceptance assumption $D_s(\bar{\mu}_{n,s}) \geq \xi \log \frac{2n}{\delta}$ implies, with high probability, that $D_s(0) \geq \eta^2 \log \frac{2n}{\delta}$ which was used in (4.2). This computation follows immediately from Lemma 2 and the fact that $\mathbb{E}D_s(x)$ is maximized at $x = 0$.

It remains to prove that our empirical criterion can never accept the interval with its center $\hat{\mu}_{n,s}$ satisfying $|\hat{\mu}_{n,s}| > 8s$. To do so we observe that if $|\bar{\mu}_{n,s}| > 8s$ then the interval $A_{8s}(\bar{\mu}_{n,s})$ does not contain $\mu = 0$ and in the acceptance criterion we should compare with $D_s(0)$. Assuming that $\eta > 2\kappa_2$, where $\kappa_2$ is defined in Lemma 2 and using that $\mathbb{E}D_s(x)$ is maximized at 0, we have on
the event where the inequalities of Lemma 2 hold

\[
D_s(\mu_{n,s}) - \eta \sqrt{D_s(\mu_{n,s}) \log \frac{2n}{\delta}} - \eta \log \frac{2n}{\delta} < \mathbb{E}[D_s(\mu_{n,s})|X_1,\ldots,X_n] - \kappa_2 \sqrt{D_s(0) \log \frac{2n}{\delta}} - \kappa_2 \log \frac{2n}{\delta} \\
\leq \mathbb{E}[D_s(\bar{\mu}_{n,s})|X_1,\ldots,X_n] - \kappa_2 \sqrt{D_s(0) \log \frac{2n}{\delta}} - \kappa_2 \log \frac{2n}{\delta} \\
\leq \mathbb{E}D_s(0) - \kappa_2 \sqrt{D_s(0) \log \frac{2n}{\delta}} - \kappa_2 \log \frac{2n}{\delta} \\
\leq D_s(0).
\]

Therefore, \(D_s(\mu_{n,s}) - \eta \sqrt{D_s(\mu_{n,s}) \log \frac{2n}{\delta}} - \eta \log \frac{2n}{\delta} < \max_{x \in \mathbb{R},|x-\mu_{n,s}| \geq 8s} D_s(x)\), which implies that the interval \(A_s(\mu_{n,s})\) is rejected.

**The adaptive estimator**

We are now ready to define a fully adaptive estimator that achieves a performance that is at least as good – up to a constant factor – as the best of our bounds for the median (Proposition 1) and the modal interval with optimally chosen length (Proposition 2).

We observe a sample of independent random variables \(X_1,\ldots,X_n\). Fix the desired confidence level \(\delta \in (0,1)\). We output the estimator \(\bar{\mu}\) defined as follows:

- Fix \(\alpha = \sqrt{2 \log \frac{6}{\delta}}\) and compute the \(\alpha\)-median interval \(I_\alpha\).

- Let \(\mu\) be the midpoint of the interval

\[
A_{s_0}(\mu_{n,s}) \cap I_\alpha, \quad (4.4)
\]

where \(\mu_{n,s}\) is defined by (3.1) and let \(\mu\) be the midpoint of the interval \(I_\alpha\) if the set (4.4) is empty.

- Return \(\mu\).

**Remark.** In practice there is no need to search through all \(s > 0\) in (4.4). One may discretize and consider only \(s_i = 2^{-i}|I_\alpha|\) for integers \(i \geq 0\). Also, due to Lemma 2 we may essentially replace \(\mathbb{E}D_s(x)\) by \(D_s(x)\) in the steps of the proof.
where admissibility is used. That is, one may instead consider the random admissibility condition of the form

\[ m_s \gtrsim \sqrt{D_s(\mu) \log \frac{2n}{\delta} + \log \frac{2n}{\delta}}. \]

Due to the discrete nature of the sample, only a finite number of values \( D_s(\mu) \) is possible and in the set (4.4) one may consider only at most \( \binom{\sqrt{D_s(\mu)} \log \frac{2n}{\delta}}{n} \delta \) values of \( s \) that correspond to the distances between pairs of points. For the sake of brevity we omit the straightforward details of the analysis of the discretized estimator and focus on the estimator defined above.

**Theorem 1.** Let Assumptions [A] and [B] be satisfied. Fix \( \delta \in (0,1/2) \) such that \( 128 \log \frac{\delta}{\delta} \leq n \). There is a numerical constant \( c_1 > 0 \) such that, with probability at least \( 1 - \frac{2}{\delta} \), the estimator \( \hat{\mu} \) defined above satisfies

\[ |\hat{\mu} - \mu| \leq c_1 \min \left\{ \overline{\sigma}(\delta), \beta^{-1} \log \left( \frac{n}{\delta} \right) \max_{1 \leq j \leq 8} \frac{8\alpha \sqrt{n} + 1 - j}{\sum_{i=1}^{n} \sigma_i} \right\}, \]

where \( \overline{\sigma}(\delta) \) is given by Definition [I].

**Proof.** Recalling that \( |I_\alpha| \) is a random variable, consider the event \( E_1 \),

\[ \overline{\sigma}(\delta) \leq |I_\alpha|. \]

On the complementary event \( \overline{E}_1 \) we have that the solution based on the \( \alpha \)-median interval is better than what one can get with the modal interval estimator. In particular, since \( \hat{\mu} \) always returns a point in \( I_\alpha \), the proof is complete by Proposition [I].

Otherwise, we focus on the event \( E_1 \). Let \( E_2 \) be the event that every accepted interval \( A_s(\hat{\mu}_{n,s}) \) satisfies \( \mu \in A_{8s}(\hat{\mu}_{n,s}) \). By Proposition [3] it holds that \( \mathbb{P}(E_2) \geq 1 - \delta \). Therefore, on \( E_2 \), we have either

\[ \mu \in \bigcap_{0 \leq s \leq |I_\alpha|} A_{8s}(\hat{\mu}_{n,s}), \quad (4.5) \]

or there are no accepted intervals in this range. The latter cannot be true on the event \( E_1 \cap E_2 \) since \( \overline{\sigma}(\delta) \leq |I_\alpha| \) and \( A_{8s}(\hat{\mu}_{n,s}) \) is accepted. Therefore, the intersection of intervals in (4.5) is non-empty and its length is bounded by \( 16\overline{\sigma}(\delta) \). Thus, on the event \( E_1 \cap E_2 \) we have \( |\hat{\mu} - \mu| \leq 16\overline{\sigma}(\delta) \). The claim follows by the union bound.

### 5 Examples and a comparison with existing results

To demonstrate the meaning of the derived performance bounds, in this section we discuss several natural examples and compare our results with existing general bounds. As already mentioned, our adaptive estimator is closely
related to the estimator of Chierichetti et al. (2014) and to the hybrid estimator of Pensia et al. (2019). Apart from the full adaptivity of our estimator, let us emphasize some technical differences with the latter work (which generalizes the results in Chierichetti et al. (2014)):

- Even though the results in (Pensia et al.; 2019) work under milder assumptions, their bounds depend on the distribution through the quantity $r_k$ which should be “manually” computed in each particular case. In contrast, our results require that Assumptions $A$ and $B$ hold, but because of this the resulting bound depends explicitly on the standard deviations $\sigma_1, \ldots, \sigma_n$.

- Our analysis of the modal interval estimator is sharper. In particular, while by Pensia et al. (2019, Theorem 1) the modal interval estimator can never choose a center that has on average less than $\frac{1}{2} \mathbb{E} D_s(\mu)$ observations, our analysis uses the sharper property that the modal interval estimator never chooses a center that has, on the average, less than $\mathbb{E} D_s(\mu) - c \sqrt{\mathbb{E} D_s(\mu)}$ observations, for some $c > 0$ up to logarithmic factors.

5.1 Examples

Most of our examples appear in (Pensia et al.; 2019) and (Liang and Yuan; 2020). We show that our bounds written in terms of $\sigma_1, \ldots, \sigma_n$ are not worse than any of the previous bounds depending on some more involved distribution dependent quantities, often achieved by non-adaptive estimators. In all examples we only consider the Gaussian case, that is, we assume $X_i \sim \mathcal{N}(\mu, \sigma_i^2)$. Also, for the sake of presentation we fix the allowed probability of error to be $\delta = \frac{1}{n}$.

Example. (Equal variances.) In the simplest case we have $\sigma_i = \sigma$ for $i \in [n]$. In this example the median interval alone recovers the optimal error rate $\tilde{O}\left(\frac{\sigma}{\sqrt{n}}\right)$. Therefore, our adaptive algorithm mimics the optimal behavior of the sample mean in the i.i.d. scenario.

Example. (Two variances.) Consider the case where $\sigma_i = \sigma$ for $i \in [m]$ and $\sigma_i = \sigma' > \sigma$ for $i \in [n] \setminus [m]$.

There are different cases and we consider the most interesting regimes. First, if $m \gtrsim \sqrt{n \log n}$ the median gives the rate $\tilde{O}\left(\frac{\sigma}{\sqrt{n}} + \frac{\sqrt{n}}{(n-m)(\sigma')^{-1}}\right)$ and the interval algorithm can always guarantee the error $O(\sigma)$ since the interval of length $\sigma$ is admissible. Next we consider $m \lesssim \sqrt{n \log n}$. The median gives the rate $\tilde{O}\left(\frac{\sigma'}{\sqrt{n}}\right)$ in this regime and the interval of length $O(\sigma)$ is admissible if $m \gtrsim \sqrt{\frac{\sigma'}{\sqrt{n}}} n \log n + \log n$. In particular, an application of Theorem 1 and shows
that, with probability at least $1 - \frac{1}{n}$,

$$|\hat{\mu} - \mu| = \begin{cases} \tilde{O}\left(\frac{\sqrt{n}}{m^\alpha - 1 + (n-m)(\sigma')^{-1}}\right), & \text{if } m \gtrsim \sqrt{n} \log n; \\ \tilde{O}\left(\sigma \wedge \frac{\sigma'}{\sqrt{n}}\right), & \text{if } \sqrt{\frac{n}{\log n}} \log n + \log n \lesssim m \lesssim \sqrt{n} \log n. \end{cases}$$

**Example.** ($\alpha$-mixture distributions.) This is a particular case of the example of two variances above, with $m = c \lceil \log n \rceil$, for some $c > 0$; $\sigma = 1$ and $\sigma' = n^\alpha$ for some $\alpha > 0$. This example was thoroughly studied in Pensia et al. (2019). When $\alpha < 1$ the analysis of the sample median in the example above gives, with probability at least $1 - \frac{1}{n}$,

$$|\hat{\mu} - \mu| = \tilde{O}(n^{\alpha - 1/2}),$$

otherwise, for $\alpha \geq 1$ provided that $c$ is a large enough numerical constant we have

$$|\hat{\mu} - \mu| = O(1).$$

Therefore, our algorithm recovers the best known rates in Pensia et al. (2019, Table 1 and Proposition 5), in an adaptive manner.

**Example.** (Quadratic variances.) In this setup we assume that for some constant $c > 0$, $\sigma_i^2 = c^2 i^2$. In this case, an interval of length $s = cj$ is admissible if

$$j \gtrsim \sqrt{\sum_{i=j}^{n} i \log n + \log n}.$$ 

Using $\sum_{i=j}^{n} \frac{i}{i} \lesssim j \log n$, we see that an interval of length proportional to $\log n$ is admissible. A simple computation shows that the median interval can produce an error $\tilde{O}(\sqrt{n})$ (see also Pensia et al. (2019, Proposition 4)). Finally, an application of Theorem 1 gives, with probability at least $1 - \frac{1}{n}$,

$$|\hat{\mu} - \mu| = O(\log n).$$

This improves upon the bound of Pensia et al. (2019, Table 1 and Proposition 5) where for the same model an arbitrarily small polynomial error is established.

**Example.** (The subset-of-signals model.) In this setup the only assumption is that, for some $m < n$, at least $m$ out of $n$ variances are less or equal to one. In other words, $\sigma_m \leq 1$. The subset-of-signals model was studied by Liang and Yuan (2020). The authors prove that if $m \gtrsim \sqrt{n} \log n$, then there is
an estimator $\tilde{\mu}$ based on iterative truncations (first studied in \cite{YuanLi:20}) such that, with probability at least $1 - \frac{1}{n}$,

$$|\tilde{\mu} - \mu| \lesssim \frac{\sqrt{n \log n}}{m}.$$  

Assuming that $m \gtrsim \sqrt{n \log n}$, we have by Proposition 1 and Theorem 1, that, with probability at least $1 - \frac{1}{n}$,

$$|I_{\alpha}| \lesssim \frac{\sqrt{n} (\log n)^{3/2}}{m}$$

and thus, $|\tilde{\mu} - \mu| = \tilde{O}\left(\frac{\sqrt{n}}{m}\right)$. This shows that the sample median (and hence our general adaptive estimator) performs as well as the algorithm of \cite{LiangYuan:20}, up to a logarithmic factor. The advantage of the median is that its complexity is linear in the number of observations \cite{Blum:73} whereas the iterative truncation algorithm is more complex. Moreover, the iterative truncation algorithm of \cite{LiangYuan:20} depends on some parameters of the problem as well as on an initialization. We additionally remark that according to \cite{LiangYuan:20}, the hybrid estimator of Pensia et al. (2019) also recovers the rate $\tilde{O}\left(\frac{\sqrt{n}}{m}\right)$ in the subset-of-signals model.

### 5.2 A comparison with some general bounds

Finally, we compare our results with several recent general bounds. Our main conclusion is that, apart from the logarithmic factors and at least in the case of Gaussian data, our adaptive estimator performs at least as well as the best known guarantees in the literature. We emphasize again that our estimator does not depend on any parameters of the problem whereas the best known algorithms require some kind of parameter tuning.

**The result of Xia on the median of Gaussians**

\cite{Xia:19} analyzed the sample median of independent, not necessarily identically distributed random variables with the same median. For the sake of an easier comparison, we only consider here the case of normal random variables. The following result appears in \cite{Xia:19, Corollary 6}.

**Proposition 4.** Consider independent $X_1, \ldots, X_i$ such that $X_i \sim \mathcal{N}(\mu, \sigma_i^2)$. Assume that $\delta \in (0, 1)$ satisfies

$$\frac{\sqrt{n \log \frac{1}{\delta}}}{\sum_{i=1}^n \sigma_i^{-1}} \leq \frac{7 \sqrt{2} \sigma_1}{10}. \quad (5.1)$$

Then, with probability at least $1 - \delta$,

$$|X_{(n/2)} - \mu| \leq \frac{10 \sqrt{2 n \log \frac{1}{\delta}}}{\sum_{i=1}^n \sigma_i^{-1}}.$$
At first glance the result of Proposition 4 looks stronger than what is given by Corollary 1 in the special case of Gaussians. Indeed, it does not have the \( \log n \) factor and has a better dependence on \( \log \frac{1}{\delta} \). The main difference comes from the assumption (5.1) which is more restrictive than the only assumption \( 128 \log \frac{6}{\delta} \leq n \) of Corollary 1. Indeed, in the most favourable case when \( \sigma_i = \sigma \) for \( i \in [n] \), the condition (5.1) implies \( \log \frac{1}{\delta} \leq \left( \frac{7\sqrt{2}}{10} \right)^2 n \) which coincides with our assumption up to absolute constants. However, for small \( \sigma_1 \) the assumption (5.1) requires \( \delta \to 1 \) whereas our bound is not sensitive to the approximately \( \sqrt{n} \log \frac{1}{\delta} \) smallest variances. The following result shows that the condition (5.1) simplifies the bound of Proposition 1 making it almost the same as the result of Proposition 4, up to logarithmic factors.

**Corollary 2.** Fix \( \delta \in (0, 1) \) such that \( 128 \log \frac{6}{\delta} \leq n \) and set \( \alpha = \sqrt{2 \log \frac{6}{\delta}} \). Assume that there is \( 0 < c < 1 \) such that

\[
8\sqrt{2n \log \frac{6}{\delta}} \leq c \sigma_1.
\]

Under the assumptions of Proposition 4 we have, with probability at least \( 1 - \delta \),

\[
|I_\alpha| \leq 64e \sqrt{2} \left( \log \frac{3}{\delta} \vee \log (n + 1) \right) \beta^{-1} \frac{\sqrt{2n \log \frac{6}{\delta}}}{(1 - c) \sum_{i=1}^{n} \sigma_i^{-1}}.
\]

**Proof.** The proof is based on elementary comparisons. Fix \( j \leq 8\alpha \sqrt{n} \). Then

\[
\sum_{i=1}^{n} \sigma_i^{-1} \geq \sum_{i=8\alpha \sqrt{n}+1}^{n} \sigma_i^{-1} = \sum_{i=1}^{8\alpha \sqrt{n}} \sigma_i^{-1} - \sum_{i=1}^{8\alpha \sqrt{n}} \sigma_i^{-1} \geq 8\alpha \sqrt{n} \sigma_1^{-1} (c^{-1} - 1) \sum_{i=1}^{8\alpha \sqrt{n}} \sigma_i^{-1}.
\]

This implies

\[
c^{-1} \sum_{i=j}^{n} \sigma_i^{-1} \geq (c^{-1} - 1) \sum_{i=j}^{n} \sigma_i^{-1} + (c^{-1} - 1) \sum_{i=1}^{8\alpha \sqrt{n}} \sigma_i^{-1} \geq (c^{-1} - 1) \sum_{i=1}^{n} \sigma_i^{-1}.
\]

Combining these inequalities, we obtain

\[
\max_{1 \leq j \leq 8\alpha \sqrt{n}} \frac{8\alpha \sqrt{n} - j + 1}{\sum_{i=j}^{n} \sigma_i^{-1}} \leq \frac{1}{1 - c} \max_{1 \leq j \leq 8\alpha \sqrt{n}} \frac{8\alpha \sqrt{n} - j + 1}{\sum_{i=1}^{n} \sigma_i^{-1}} = \frac{1}{1 - c} \frac{8\alpha \sqrt{n}}{\sum_{i=1}^{n} \sigma_i^{-1}}.
\]

The result follows.
The bound of Chierichetti, Dasgupta, Kumar and Lattanzi.

Chierichetti et al. (2014, Theorem 4.1) introduce an estimator $\tilde{\mu}$ such that for $X_i \sim \mathcal{N}(\mu, \sigma_i)$, with probability at least $1 - \frac{1}{n}$,

$$|\tilde{\mu} - \mu| = \tilde{O}(\sigma_{\log n} \sqrt{n}).$$

(5.2)

The hybrid estimator of Pensia et al. (2019, Theorem 6 and Lemma 1) satisfies a similar performance bound if the parameters are chosen in a specific way. The next result shows that the adaptive estimator introduced in this note achieves this bound without any additional parameter tuning. Moreover, the result follows from our general bounds written in terms of $\sigma_1, \ldots, \sigma_n$.

Proposition 5. Let Assumptions $A$ and $B$ hold and assume that $\log n$ is integer. There is a constant $c = c(\beta, \phi(0)) > 1$ such that the adaptive estimator of Theorem 1 satisfies for large enough $n$ that, with probability at least $1 - \frac{1}{n}$,

$$|\hat{\mu} - \mu| \leq c \left( \sigma_{c \log n} \sqrt{n \log^{3/2} n} \right).$$

The proof is based on some elementary but tedious computations, see Appendix B.

6 Concluding remarks

In this note we construct a fully adaptive estimator for the common mean of independent, not necessarily identically distributed random variables and provide performance guarantees that hold under certain assumptions for the underlying distribution. The key assumptions are that the distributions are symmetric around the mean and the underlying densities are unimodal. However, even in the simplest case of normal random variables, the problem is not fully understood. In particular, as far as we know, no general nontrivial lower bounds are available. It is not difficult to prove that no estimator can have an expected error smaller than that of the maximum likelihood estimator that “knows” the variance of each sample point, that is, $\left( \sum_{i=1}^{n} \sigma_i^{-2} \right)^{-1/2}$. In the absence of knowledge of the $\sigma_i$, the problem becomes significantly harder. It remains an interesting challenge to prove general lower bounds that are much larger than the trivial bound $\left( \sum_{i=1}^{n} \sigma_i^{-2} \right)^{-1/2}$. In fact, we think that, up to logarithmic factors, the upper bound of Theorem 1 is essentially tight for most interesting values of the parameters. However, the full picture is surely more complex. For example, in some particular ranges of the parameters it is easy to improve on Theorem 1. To illustrate such an example, consider the case of two variances discussed in Section 5, that is, when $\sigma_i = \sigma$ for $i \in [m]$ and $\sigma_i = \sigma' > \sigma$ for $i \in [n] \setminus [m]$. Suppose that $\sigma \sqrt{\log m} \ll \sigma'/n$. In this case, with high probability, the modal interval of length $s = 3\sigma \sqrt{\log m}$ contains all of $X_1, \ldots, X_m$ but none of $X_{m+1}, \ldots, X_n$. In this case, instead of outputting the center of the modal
interval, by averaging the points falling in it, one obtains an error of the order 
\(O(\sigma/\sqrt{m})\), as opposed to \(O(\sigma)\) guaranteed by Theorem in this case.

Even our analysis of the sample median leaves room for improvement. In
particular, we think that part (iii) of Assumption may be weakened. While
it is obviously necessary to assume that the density of the \(X_i\) are bounded
away from zero near the mean (consider the case of independent Rademacher
random signs in the i.i.d. case), the exponential tail condition implied by this
assumption seems unnecessary. Indeed, Corollary 12 in deals with
the heavy-tailed Cauchy distribution.

Another interesting challenge is to gain an understanding of more general
cases when \(X_1,\ldots, X_n\) are independent, they have the same mean, but their
distribution may not be symmetric or unimodal.

Finally, we mention that the model studied in this note is closely related to
the model of heteroscedastic linear regression with fixed design. In this model
it is assumed that one observes, for \(i \in [n]\),

\[
Y_i = \langle x_i, \beta \rangle + \xi_i
\]

where \(\beta \in \mathbb{R}^d\) is the target parameter, \(x_i \in \mathbb{R}^d\) are deterministic design vectors,
and \(\xi_i \sim \mathcal{N}(0, \sigma_i)\) are independent noise variables. In order to provide some
reasonable guarantees for this model, one usually makes some additional as-
sumptions. In a classical model (see, for instance, (Fuller and Rao, 1978)) it
is assumed that the values of \(\sigma_i\) are arbitrary, but there are enough repet-
tions of each observation available so that one can estimate the values of \(\sigma_i\).
Once the values of \(\sigma_i\) and their assignments to the observations are (almost)
known, one may use the weighted mean described in the introduction which
achieves (almost) optimal performance. Another line or research which can
be attributed, among other papers, to the early work of Carroll and Ruppert
(1982), is where some additional assumptions on \(\sigma_i\) are made. For example,
they are increasing according to some law. Our model can be seen as a partic-
ular case of heteroscedastic linear regression in dimension one, where we ad-
ditionally assume that the design \(x_i\) is the same for all \(i\). However, these sim-
plifications are compensated by the fact that we make neither the assumption
on the repeated observations nor the assumption that the \(\sigma_i\) follow a partic-
ular functional form. Finally, our estimators are invariant to the permuta-
tion of the elements of the sample and thus cannot exploit the monotonicity of the
standard deviations.

A  Ratio-type \(\text{vc}\) bounds for non-identically distributed
entries

In this section we provide high probability ratio-type \(\text{vc}\) bounds (originally
due to (Vapnik and Chervonenkis, 1974, Theorem 12.2)) for independent but
non-identically distributed random variables. A bound of a similar type was
proved in (Pensia et al., 2019, Lemma 2) though their result is not sufficient
for our purposes. Consider a set $\mathcal{F}$ of $[0,1]$-valued functions defined on a domain $\mathcal{X}$ such with vc-dimension equal to $d$. Recall that the vc dimension is the largest integer $d$ such that there are $x_1, \ldots, x_d \in \mathcal{X}$ satisfying $|(\{f(x_1), \ldots, f(x_d)\} : f \in \mathcal{F})| = 2^d$. The proof of the next technical lemma is a quite straightforward generalization of similar bounds for the i.i.d. case. The analysis is based on localization techniques for empirical processes. We refer, for instance, to (Bartlett, Bousquet and Mendelson; 2005, Corollary 3.7) and to (Bousquet and Zhivotovskiy; 2019) for some similar results in the context of vc classes.

**Lemma 2.** Let $X_1, \ldots, X_n$ be independent but not necessary identically distributed random variables taking their values in $\mathcal{X}$. Assume that the class $\mathcal{F}$ of $[0,1]$-valued functions has the vc dimension $d$. Then there are numerical constants $\kappa_1, \kappa_2 > 0$ such that for any $\delta \in (0,1)$, with probability at least $1 - \delta$, for all $f \in \mathcal{F}$,

$$\left| \sum_{i=1}^{n} (f(X_i) - \mathbb{E}f(X_i)) \right| \leq \kappa_1 \left( \sqrt{\sum_{i=1}^{n} \mathbb{E}f(X_i)} \left( d \log \frac{n}{d} + \log \frac{1}{\delta} \right) + d \log \frac{n}{d} + \log \frac{1}{\delta} \right)$$

(A.1)

and

$$\left| \sum_{i=1}^{n} (f(X_i) - \mathbb{E}f(X_i)) \right| \leq \kappa_2 \left( \sqrt{\sum_{i=1}^{n} f(X_i)} \left( d \log \frac{n}{d} + \log \frac{1}{\delta} \right) + d \log \frac{n}{d} + \log \frac{1}{\delta} \right).$$

(A.2)

**Proof.** Without loss of generality we may assume that $0 \in \mathcal{F}$ since by adding $f \equiv 0$ to the class the vc dimension increases by at most one which can be absorbed by choosing slightly larger values of $\kappa_1, \kappa_2 > 0$. Consider the star-shaped hull of $\mathcal{F}$ around zero, that is, the class $\mathcal{H}$ of $[0,1]$-valued functions defined as

$$\mathcal{H} = \{ \alpha f : f \in \mathcal{F}, \alpha \in [0,1] \}.$$

For $h \in \mathcal{H}$, we denote $Ph^2 = \frac{1}{n} \sum_{i=1}^{n} \mathbb{E}h(X_i)^2$. Fix any $\delta \in (0,1)$ and consider the fixed point

$$\gamma(\lambda, \delta) = \inf \left\{ s > 0 : \mathbb{P} \left( \sup_{h \in \mathcal{H}, Ph^2 \leq s^2} \left| \sum_{i=1}^{n} (h(X_i) - \mathbb{E}h(X_i)) \right| \leq \lambda ns^2 \right) \geq 1 - \delta \right\},$$

where $\lambda > 0$ is a numerical constant specified below. By the definition of $\gamma(\lambda, \delta)$ we have, with probability at least $1 - \delta$,

$$\sup_{h \in \mathcal{H}, Ph^2 \leq \gamma(\lambda, \delta)^2} \left| \sum_{i=1}^{n} (h(X_i) - \mathbb{E}h(X_i)) \right| \leq \lambda n \gamma(\lambda, \delta)^2. \quad (A.3)$$

\footnote{In particular, our result covers some values of their parameter $t$ that are not allowed in (Pensia et al. 2019, Lemma 2).}
Fix any \( h \in \mathcal{H} \) such that \( Ph^2 \geq \gamma(\lambda, \delta)^2 \). Since \( \mathcal{H} \) is star-shaped, we have that \( h' = hy(\lambda, \delta)/\sqrt{Ph^2} \in \mathcal{H} \) and \( P(h')^2 = \gamma(\lambda, \delta)^2 \), which, applying (A.3) for \( h' \), implies on the same event (and the same holds simultaneously for any such \( h \))

\[
\left| \sum_{i=1}^{N} (h(X_i) - \mathbb{E}h(X_i)) \right| \leq \lambda \eta \gamma(\lambda, \delta) \sqrt{Ph^2} .
\]

The last inequality, combined with (A.3), implies

\[
\sup_{h \in \mathcal{H}} \left| \sum_{i=1}^{N} (h(X_i) - \mathbb{E}h(X_i)) \right| \leq \lambda \eta \gamma(\lambda, \delta) \sqrt{Ph^2} + \lambda \eta \gamma(\lambda, \delta)^2 .
\]

(A.4)

Finally, we need to prove an upper bound for \( \gamma(\lambda, \delta) \). Denoting \( \mathcal{H}' = \mathcal{H} \cup (-\mathcal{H}) \), we have

\[
\sup_{h \in \mathcal{H}', Ph^2 \leq \lambda} \left| \sum_{i=1}^{N} (h(X_i) - \mathbb{E}h(X_i)) \right| = \sup_{h \in \mathcal{H}', Ph^2 \leq \lambda} \left( \sum_{i=1}^{N} (h(X_i) - \mathbb{E}h(X_i)) \right) .
\]

By Giné and Nickl (2016, Theorem 3.16) (see inequality (3.128) there which is relaxed in what follows by using \( \sqrt{2(2\mathbb{E}Z + V_n)X} = \sqrt{2V_n x + x + \mathbb{E}Z} \)), since almost surely \( |h(X_i) - \mathbb{E}h(X_i)| \leq 1 \) and by fixing \( x = \log \frac{1}{\delta} \), we have, with probability at least \( 1 - \delta \),

\[
\sup_{h \in \mathcal{H}', Ph^2 \leq \lambda} \left( \sum_{i=1}^{N} (h(X_i) - \mathbb{E}h(X_i)) \right) \leq 2 \mathbb{E} \sup_{h \in \mathcal{H}', Ph^2 \leq \lambda} \left| \sum_{i=1}^{N} (h(X_i) - \mathbb{E}h(X_i)) \right| + s \sqrt{n \log \frac{1}{\delta} + \frac{5}{2} \log \frac{1}{\delta}} .
\]

(A.5)

Finally, using the symmetrization inequality (Ledoux and Talagrand, 2013) we have

\[
\mathbb{E} \sup_{h \in \mathcal{H}', Ph^2 \leq \lambda} \left( \sum_{i=1}^{N} (h(X_i) - \mathbb{E}h(X_i)) \right) \leq 2 \mathbb{E} \sup_{h \in \mathcal{H}', Ph^2 \leq \lambda} \left( \sum_{i=1}^{N} \varepsilon_i h(X_i) \right) ,
\]

where \( \varepsilon_1, \ldots, \varepsilon_n \) are i.i.d. Rademacher random variables with \( \mathbb{P}(\varepsilon_i = 1) = \mathbb{P}(\varepsilon_i = -1) = 1/2 \). Conditioning on \( X_1, \ldots, X_n \), we may use Dudley’s entropy integral bound (see, for instance, Boucheron et al. (2013)). First, we estimate the covering numbers of the set \( \mathcal{H} \) with respect to the (random) distance \( \rho(f, g) = \sqrt{\sum_{i=1}^{n} (f(X_i) - g(X_i))^2/n} \). Denote

\[
\text{diam}(n, s) = \sup_{f, h \in \mathcal{H}, Ph^2 \leq \lambda} \rho(f, h) .
\]

By the bound of Haussler (1995), the covering number of \( \mathcal{F} \) at scale \( r \) is upper bounded by \( e(d + 1) \left( \frac{2r}{\rho} \right)^d \) and by a standard argument we have that the covering number of \( \mathcal{H} \) is upper bounded by \( e(d + 1) \left( \frac{8r}{\rho} \right)^d \left( 1 + \sqrt{\frac{2r}{\rho}} \right) \) (see Bartlett et al.)
Proof of Corollary 3.7). Therefore, by the Dudley’s bound we have, for some constants $c_1, c_2 > 0$,

$$
\mathbb{E} \sup_{h \in \mathcal{H}, \|h\|_2 \leq s^2} \left( \sum_{i=1}^{n} \varepsilon_i h(X_i) \right) = \mathbb{E} \sup_{h \in \mathcal{H}, \|h\|_2 \leq s^2} \left| \sum_{i=1}^{n} \varepsilon_i h(X_i) \right| \leq c_1 \sqrt{n} \mathbb{E} \int_{0}^{\text{diam}(n,s)} \sqrt{d \log \frac{e}{r}} dr
$$

$$
\leq c_2 \sqrt{n} \text{diam}(n,s) \sqrt{d \log \frac{e}{\text{diam}(n,s)}} \left( 1_{\text{diam}(n,s) \geq \sqrt{d/n} + 1} + 1_{\text{diam}(n,s) < \sqrt{d/n}} \right)
$$

By Jensen’s inequality combined with the standard symmetrization and contraction inequalities (Ledoux and Talagrand, 2013) we have, for some $c_3 > 0$,

$$
\sqrt{n} \text{diam}(n,s) \leq \sqrt{2 \mathbb{E} \sup_{h \in \mathcal{H}, \|h\|_2 \leq s^2} \sum_{i=1}^{n} h^2(X_i)}
$$

$$
\leq \sqrt{2 \mathbb{E} \sup_{h \in \mathcal{H}, \|h\|_2 \leq s^2} \sum_{i=1}^{n} (h^2(X_i) - \mathbb{E} h^2(X_i)) + 2ns^2}
$$

$$
\leq c_3 \left( \mathbb{E} \sup_{h \in \mathcal{H}, \|h\|_2 \leq s^2} \left( \sum_{i=1}^{n} \varepsilon_i h(X_i) \right) + \sqrt{ns} \right).
$$

Combining the last two arguments, we have, for some $c_4 > 0$,

$$
\mathbb{E} \sup_{h \in \mathcal{H}, \|h\|_2 \leq s^2} \left( \sum_{i=1}^{n} \varepsilon_i h(X_i) \right) \leq c_4 \left( s \sqrt{dn \log \frac{n}{d}} + d \sqrt{\log \frac{n}{d}} \right) . \quad (A.6)
$$

Finally, combining \(A.5\), \(A.6\) and adjusting the constant $\lambda$ we have, for some $c_5 > 0$, that

$$
\gamma(\lambda, \delta) \leq c_5 \sqrt{\frac{d \log \frac{n}{d} + \log \frac{1}{\delta}}{n}},
$$

which implies our first bound \(A.1\) by \(A.4\).

To prove \(A.2\) we use that for $a, b, x > 0$, $\sqrt{ab} \leq \frac{a}{2x} + \frac{bx}{2}$. This implies

$$
\kappa_1 \left( \sum_{i=1}^{n} \mathbb{E} f(X_i) \right) \left( d \log \frac{n}{d} + \log \frac{1}{\delta} \right) \leq \frac{1}{2} \sum_{i=1}^{n} \mathbb{E} f(X_i) + \frac{\kappa_2^2}{2} \left( d \log \frac{n}{d} + \log \frac{1}{\delta} \right), \quad (A.7)
$$

which, by \(A.1\), implies that on the same event where \(A.1\) holds,

$$
\frac{1}{2} \sum_{i=1}^{n} \mathbb{E} f(X_i) \leq \frac{n}{2} f(X_i) + \left( \kappa_1^2/2 + \kappa_1 \right) \left( d \log \frac{n}{d} + \log \frac{1}{\delta} \right).
$$

Plugging this into \(A.1\) and adjusting the constant $\kappa_2$ proves \(A.2\).
B Proof of Proposition 5

To simply the presentation we assume that the values \( \log n, n^{1/3}, n^{1/6}, \ldots \) corresponding to the indexes are always integers. It follows from Theorem 1 that there exists a constant \( C > 0 \) (which only depends on \( \beta \) and \( \phi(0) \)) such that, with the same probability of error, the adaptive estimator has an error at most

\[
C \min \left( \frac{\sqrt{n} \log^{3/2} n}{\sum_{i > C} \frac{1}{\sqrt{n \log n \sigma_i}}}, \sigma_m \right),
\]

where \( m \) is any integer that satisfies

\[
m \geq C \max \left( \sqrt{\sigma_m \sum_{i \geq m} \frac{1}{\sigma_i} \log n, \log n} \right). \tag{B.1}
\]

Therefore, it is sufficient to prove that for all sequences \( \sigma_i \),

\[
\min \left( \frac{\sqrt{n} \log^{3/2} n}{\sum_{i > C} \frac{1}{\sqrt{n \log n \sigma_i}}}, \sigma_m \right) \lesssim \sqrt{n} (\log^{3/2} n) \sigma_C \log n.
\]

If

\[
\frac{\sqrt{n} \log^{3/2} n}{\sum_{i > C} \frac{1}{\sqrt{n \log n \sigma_i}}} \leq \sqrt{n} (\log^{3/2} n) \sigma_C \log n,
\]

then we are done, so we may assume

\[
\frac{\sqrt{n} \log^{3/2} n}{\sum_{i > C} \frac{1}{\sqrt{n \log n \sigma_i}}} > \sqrt{n} (\log^{3/2} n) \sigma_C \log n,
\]

or, equivalently,

\[
\sum_{i > C} \frac{1}{\sqrt{n \log n \sigma_i}} < \frac{1}{\sigma_C \log n}. \tag{B.2}
\]

It suffices to show that, when (B.2) holds, then there exists a value of \( m \) satisfying (B.1) for which \( \sigma_m \leq \sqrt{n} (\log^{3/2} n) \sigma_C \log n \).

For any \( m \leq C \sqrt{n \log n} \), we may write

\[
\sum_{i > m} \frac{1}{\sigma_i} = \sum_{i > C \sqrt{n \log n}} \frac{1}{\sigma_i} + \sum_{i \in [m, C \sqrt{n \log n}]} \frac{1}{\sigma_i}.
\]

Using (B.2), we see that \( m \) satisfies (B.1) whenever

\[
\frac{m^2}{C^2 \sigma_m} \geq \max \left( \frac{\log^2 n}{\sigma_m}, \frac{\log n}{\sigma_C \log n} + \log n \sum_{i \in [m, C \sqrt{n \log n}]} \frac{1}{\sigma_i} \right). \tag{B.3}
\]
First, note that if the first term dominates on the right-hand side of the above inequality, then $m = C \log n$ satisfies the inequality above, and therefore the new bound is at most $C \sigma_C \log n$ and our claim follows.

Hence, we may assume that the second term dominates and therefore we look for the values of $m$ such that

$$\frac{m^2}{C^2 \sigma_m} \geq \frac{\log n}{\sigma_C \log n} + \log n \sum_{i \in [m, C \sqrt{n \log n})} \frac{1}{\sigma_i}. \quad (B.4)$$

We distinguish two cases depending on which term dominates on the right-hand side: in case (i),

$$\frac{1}{\sigma_C \log n} > \sum_{i \in [m, C \sqrt{n \log n})} \frac{1}{\sigma_i},$$

while in case (ii) the opposite holds. In case (i), the right-hand side of (B.4) is at most $2 \log n/\sigma_C \log n$. Hence, we may take $m = C \log n$ to satisfy the inequality (B.1) for $n$ large enough, leading to the bound $C \sigma_C \log n$ which proves our claim.

In case (ii), the right-hand side of (B.4) is bounded by

$$2 \log n \sum_{i \in [m, C \sqrt{n \log n})} \frac{1}{\sigma_i} \leq 2C \sqrt{n} (\log^{3/2} n) \sum_{i \in [m, C \sqrt{n \log n})} \frac{1}{\sigma_i}. \quad (B.5)$$

This implies by (B.4) that the inequality (B.1) is satisfied when

$$m \geq \sqrt{2C^{3/2}} n^{1/4} (\log^{3/4} n).$$

Since for $n$ large enough

$$n^{1/3} \geq \sqrt{2C^{3/2}} n^{1/4} (\log^{3/4} n),$$

this yields the upper bound $\sigma_{m_1}$ with $m_1 = n^{1/3}$.

If $\sigma_{m_1} \leq \sqrt{n} (\log^{3/2} n) \sigma_C \log n$, then the proof is finished. Otherwise,

$$\sum_{i \in [m, C \sqrt{n \log n})} \frac{1}{\sigma_i} \leq \sum_{i \in [m, m_1]} \frac{1}{\sigma_i} + C \sqrt{n \log n} \sum_{i \in [m, m_1]} \frac{1}{\sigma_{m_1}} \leq \sum_{i \in [m_1]} \frac{1}{\sigma_i} + \frac{C}{(\log n) \sigma_C \log n}. \quad (B.6)$$

Plugging this back to (B.4), we see that in case (ii), the upper bound becomes $\sigma_m$ for any $m$ that satisfies

$$\frac{m^2}{C^2 \sigma_m} \geq \frac{\log n}{\sigma_C \log n} + \log n \sum_{i \in [m, m_1]} \frac{1}{\sigma_i}. \quad (B.7)$$

This has the same form as (B.4) but with a reduced range in the summation on the right-hand side.
We proceed the same way as above. Once again, we consider two cases. In case (iii),
\[
\frac{C + \log n}{\sigma C \log n} > \log n \sum_{i \in [m, m_1)} \frac{1}{\sigma_i},
\]
while in case (iv),
\[
\frac{C + \log n}{\sigma C \log n} \leq \log n \sum_{i \in [m, m_1)} \frac{1}{\sigma_i},
\]
In case (iii), the right-hand side of (B.7) is at most \(2(C + \log n)/\sigma C \log n\), so, just like before, we may take \(m = C \log n\) to satisfy the inequality (B.4), leading to the bound \(C \sigma C \log n\) whenever \(\log n \gtrsim C\).

In case (iv), the right-hand side of (B.7) is bounded by
\[
2\log n \sum_{i \in [m, m_1)} \frac{1}{\sigma_i} \leq 2\log n \frac{m_1}{\sigma_m} = \frac{2n^{1/3} \log n}{\sigma_m}.
\]
Thus, in this case (B.3) is satisfied for any \(m \geq 2Cn^{1/6} \log^{3/2} n\), and in particular, for \(m_2 = n^{2/9}\). If \(\sigma_{m_2} \leq \sqrt{n(\log^{3/2} n)} \sigma C \log n\), then the proof is finished. Otherwise,
\[
\sum_{i \in [m, m_1)} \frac{1}{\sigma_i} \leq \sum_{i \in [m, m_2)} \frac{1}{\sigma_i} + \frac{m_1}{\sigma_{m_2}} \leq \sum_{i \in [m, m_2)} \frac{1}{\sigma_i} + \frac{1}{n^{1/6}(\log^{3/2} n) \sigma C \log n}.
\]
Resubstituting into (B.4), we see that in case (iv), the upper bound becomes \(\sigma_m\) for any \(m\) that satisfies
\[
\frac{m^2}{C^2 \sigma_m} \geq \frac{C + \log n}{\sigma C \log n} + \frac{1}{n^{1/6}(\log^{1/2} n) \sigma C \log n} + \log n \sum_{i \in [m, m_2)} \frac{1}{\sigma_i}.
\]
We may now continue the same fashion, at each step reducing the range of the sum on the right-hand side unless at the \(j\)-th iteration \(\sigma_{m_j} \leq \sqrt{n(\log^{3/2} n)} \sigma C \log n\) and we are done. In general, at the \(j\)-th iteration, the summation is between \(m\) and \(m_j = n^{(2/3)^j/2}\). If we reach the \(j\)-th iteration such that \(m_j = C \log^{1/2} n\), we have
\[
\log n \sum_{i \in [m, m_j)} \frac{1}{\sigma_i} \leq \frac{C \log^{3/2} n}{\sigma_m},
\]
so that one may choose \(m = C \log n\) for large enough \(n\). The claim follows.
