Rank-One NMF-Based Initialization for NMF and Relative Error Bounds under a Geometric Assumption

Zhaoqiang Liu and Vincent Y. F. Tan, Senior Member, IEEE

Abstract—We propose a geometric assumption on nonnegative data matrices such that under this assumption, we are able to provide upper bounds (both deterministic and probabilistic) on the relative error of nonnegative matrix factorization (NMF). The algorithm we propose first uses the geometric assumption to obtain an exact clustering of the columns of the data matrix; subsequently, it employs several rank-one NMFs to obtain the final decomposition. When applied to data matrices generated from our statistical model, we observe that our proposed algorithm produces factor matrices with comparable relative errors vis-à-vis other NMF algorithms at a low computational cost. Finally, we show on face and text datasets that the combinations of our algorithm and several classical NMF algorithms outperform other algorithms in terms of clustering performance.

Index Terms—Nonnegative matrix factorization, Relative error bound, Clusterability, Separability, Initialization, Model selection

I. INTRODUCTION

The nonnegative matrix factorization (NMF) problem can be formulated as follows: Given a nonnegative data matrix $V \in \mathbb{R}_+^{F \times N}$ and a positive integer $K$, we seek nonnegative factor matrices $W \in \mathbb{R}_+^{F \times K}$ and $H \in \mathbb{R}_+^{K \times N}$, such that the distance (measured in some norm) between $V$ and $WH$ is minimized. Due to its non-subtractive, parts-based property which enhances interpretability, NMF has been widely used in machine learning [1] and signal processing [2] among others. In addition, there are many fundamental algorithms to approximately solve the NMF problem, including the multiplicative update algorithms [3], the alternating (nonnegative) least-squares-type algorithms [4]–[7], and the hierarchical alternating least square algorithms [8] (also called the rank-one residual iteration [9]). However, it is proved in [10] that NMF problem is NP-hard and all the basic algorithms simply either ensure that the sequence of objective functions is non-increasing or that the algorithm converges to the set of stationary points [9], [11], [12]. To the best of our knowledge, none of these algorithms is suitable for analyzing a bound on the approximation error of NMF.

In an effort to find computationally tractable algorithms for NMF and to provide theoretical guarantees on the errors of these algorithms, researchers have revisited the so-called separability assumption proposed by Donoho and Stodden [13]. An exact nonnegative factorization $V = WH$ is separable if for any $k \in \{1, 2, \ldots, K\}$, there is an $n(k) \in \{1, 2, \ldots, F\}$ such that $W(n(k), j) = 0$ for all $j \neq k$ and $W(n(k), k) > 0$. That is, an exact nonnegative factorization is separable if all the features can be represented as nonnegative linear combinations of $K$ features. It is proved in [14] that under the separability condition, there is an algorithm that runs in time polynomial in $F, N$ and $K$ and outputs a separable nonnegative factorization $V = W^*H^*$ of the number of columns of $W^*$ being at most $K$. Furthermore, to handle noisy data, a perturbation analysis of their algorithm is presented. The authors assumed that $V$ is normalized such that every row of it has unit $\ell_1$ norm and $V$ has a separable nonnegative factorization $V = WH$. In addition, each row of $V$ is perturbed by adding $\delta \ell_1$ norm to obtain a new data matrix $V'$. With additional assumptions on the noise and $H$, their algorithm leads to an approximate nonnegative matrix factorization $WH'$ of $V'$ with a provable error bound for the $\ell_1$ norm of each row of $V' - WH'$. To develop more efficient algorithms and to extend the basic formulation to more general noise models, a collection of elegant papers dealing with NMF under various separability conditions has emerged [15]–[19].

A. Main Contributions

1) Theoretical Contributions: We introduce a geometric assumption on the data matrix $V$ that allows us to correctly group columns of $V$ into disjoint subsets. This naturally suggests an algorithm that first clusters the columns and subsequently uses a rank-one approximate NMF algorithm [20] to obtain the final decomposition. We analyze the error performance and provide a deterministic upper bound on the relative error. We also consider a random data generation model and provide a probabilistic relative error bound. Our geometric assumption can be considered as a special case of the separability (or, more precisely, the near-separability) assumption [13]. However, there are certain key differences: First, because our assumption is based on a notion of clusterability [21], our proof technique is different from those in the literature that leverage the separability condition. Second, unlike most works that assume separability [15]–[19], we exploit the $\ell_2$ norm of vectors instead of the $\ell_1$ norm of vectors/matrices. Third, $V$...
does not need to be assumed to be normalized. As pointed out in [17], normalization, especially in the $\ell_1$-norm for the rows of data matrices may deteriorate the clustering performance for text datasets significantly. Fourth, we provide an upper bound for relative error instead of the absolute error. Our work is the first to provide theoretical analyses for the relative error for near-separable-type NMF problems. Finally, we assume all the samples can be approximately represented by certain special samples (e.g., centroids) instead of using a small set of salient features to represent all the features. Mathematically, these two approximations may appear to be equivalent. However, our assumption and analysis techniques enable us to provide an efficient algorithm and tight probabilistic relative error bounds for the NMF approximation (cf. Theorem 6).

2) Experimental Evaluations: Empirically, we show that this algorithm performs well in practice. When applied to data matrices generated from our statistical model, our algorithm yields comparable relative errors vis-à-vis several classical NMF algorithms including the multiplicative algorithm, the alternating nonnegative least square algorithm with block pivoting, and the hierarchical alternating least square algorithm. However, our algorithm is significantly faster as it simply involves calculating rank-one SVDs. It is also well-known that NMF is sensitive to initializations. The authors in [22], [23] use spherical k-means and an SVD-based technique to initialize NMF. We verify on several image and hyperspectral datasets that our algorithm, when combined with several classical NMF algorithms, achieves the best convergence rates and/or the smallest final relative errors. We also provide intuition for why our algorithm serves as an effective initializer for other NMF algorithms. Finally, combinations of our algorithm and several NMF algorithms achieve the best clustering performance for several face and text datasets. These experimental results substantiate that our algorithm can be used as a good initializer for standard NMF techniques.

B. Related Work

We now describe some works that are related to ours.

1) Near-Separable NMF: Arora et al. [14] provide an algorithm that runs in time polynomial in $F$, $N$ and $K$ to find the correct factor matrices under the separability condition. Furthermore, the authors consider the near-separable case and prove an approximation error bound when the original data matrix $V$ is slightly perturbed from being separable. The algorithm and the theorem for near-separable case is also presented in [16]. The main ideas behind the theorem are as follows: first, $V$ must be normalized such that every row of it has unit $\ell_1$ norm; this assumption simplifies the conical hull for exact NMF to a convex hull. Second, the rows of $H$ need to be robustly simplicial, i.e., every row of $H$ should not be contained in the convex hull of all other rows and the largest perturbation of the rows of $V$ should be bounded by a function of the smallest distance from a row of $H$ to the convex hull of all other rows. Later we will show in Section II that our geometric assumption stated in inequality (2) is similar to this key idea in [14]. Although we impose a clustering-type generating assumption for data matrix, we do not need the normalization assumption in [14], which is stated in [17] that may lead to bad clustering performance for text datasets. In addition, because we do not impose this normalization assumption, instead of providing an upper bound on the approximation error, we provide the upper bound for relative error, which is arguably more natural.

2) Initialization Techniques for NMF: Similar to k-means, NMF can easily be trapped at bad local optima and is sensitive to initialization. We find that our algorithm is particularly amenable to provide good initial factor matrices for subsequently applying standard NMF algorithms. Thus, here we mention some works on initialization for NMF. Spherical k-means (spkm) is a simple clustering method and it is shown to be one of the most efficient algorithms for document clustering [24]. The authors in [22] consider using spkm for initializing the left factor matrix $W$ and observe a better convergence rate compared to random initialization. Other clustering-based initialization approaches for NMF including divergence-based k-means [25] and fuzzy clustering [26]. It is also natural to consider using singular value decomposition (SVD) to initialize NMF. In fact, if there is no nonnegativity constraint, we can obtain the best rank-$K$ approximation of a given matrix directly using SVD, and there are strong relations between NMF and SVD. For example, we can obtain the best rank-one NMF from the best rank-one SVD (see Lemma 3), and if the best rank-two approximation matrix of a nonnegative data matrix is also nonnegative, then we can also obtain best rank-two NMF [20]. Moreover, for a general positive integer $K$, it is shown in [23] that nonnegative double singular value decomposition (ndsvd), a deterministic SVD-based approach, can be used to enhance the initialization of NMF, leading to a faster reduction of the approximation error of many NMF algorithms. The CUR decomposition-based initialization method [27] is another factorization-based initialization approach for NMF. We compare our algorithm to widely-used algorithms for initializing NMF in Section VI-B3.

C. Notations

We use upper case boldface letters to denote matrices and we use lower case boldface letters to denote vectors. We use Matlab-style notation for indexing, e.g., $V(i,j)$ denotes the entry of $V$ in the $i$-th row and $j$-th column, $V(i,:)$ denotes the $i$-th row of $V$, $V(:,j)$ denotes the $j$-th column of $V$ and $V(:,X)$ denotes the columns of $V$ indexed by $X$. $\|V\|_F$ represents the Frobenius norm of $V$ and $[N] := \{1,2,\ldots,N\}$ for any positive integer $N$. Inequalities $v \geq 0$ or $V \succeq 0$ denote element-wise nonnegativity. Let $V_1 \in \mathbb{R}^{F \times N_1}$ and $V_2 \in \mathbb{R}^{F \times N_2}$, we denote by $[V_1;V_2]$ the horizontal concatenation of the two matrices. Similarly, let $V_1 \in \mathbb{R}^{F_1 \times N}$ and $V_2 \in \mathbb{R}^{F_2 \times N}$. We denote by $[V_1;V_2]$ the vertical concatenation of the two matrices. We use $\mathbb{R}_+$ and $\mathbb{R}_{++}$ to represent the set of nonnegative and positive numbers respectively. We denote the nonnegative orthant $\mathbb{R}_+^F$ as $\mathcal{P}$. We use $\xrightarrow{p}$ to denote convergence in probability.

II. PROBLEM FORMULATION

In this section, we first present our geometric assumption and prove that the exact clustering can be obtained for the
normalized data points under the geometric assumption. Next, we introduce several useful lemmas in preparation for the proofs of the main theorems in subsequent sections.

A. Our Geometric Assumption on V

We assume the columns of V lie in K circular cones which satisfy a geometric assumption presented in (2) to follow. We define circular cones as follows:

Definition 1: Given \( \mathbf{u} \in \mathbb{R}^F \) with unit \( \ell_2 \) norm and an angle \( \alpha \in (0, \pi/2) \), the circular cone with respect to (w.r.t.) \( \mathbf{u} \) and \( \alpha \) is defined as

\[
C(\mathbf{u}, \alpha) := \left\{ \mathbf{x} \in \mathbb{R}^F \setminus \{0\} : \frac{\mathbf{x}^T \mathbf{u}}{\|\mathbf{x}\|_2} \geq \cos \alpha \right\}. \tag{1}
\]

In other words, \( C(\mathbf{u}, \alpha) \) contains all \( \mathbf{x} \in \mathbb{R}^F \setminus \{0\} \) for which the angle between \( \mathbf{u} \) and \( \mathbf{x} \) is not larger than \( \alpha \). We say that \( \alpha \) and \( \mathbf{u} \) are respectively the size angle and basis vector of the circular cone. In addition, the corresponding truncated circular cone in nonnegative orthant is \( C(\mathbf{u}, \alpha) \cap \mathcal{P} \).

We assume that there are \( K \) truncated circular cones \( C_1 \cap \mathcal{P}, \ldots, C_K \cap \mathcal{P} \) with corresponding basis vectors and size angles, i.e., \( C_k := C(\mathbf{u}_k, \alpha_k) \) for \( k \in [K] \). Let \( \beta_{ij} := \arccos \left( \mathbf{u}_i^T \mathbf{u}_j \right) \). We make the geometric assumption that the columns of our data matrix \( \mathbf{V} \) lie in \( K \) truncated circular cones which satisfy

\[
\min_{i,j \in [K], i \neq j} \beta_{ij} > \max_{i,j \in [K], i \neq j} \{ \alpha_i + 3\alpha_j, 3\alpha_i + \alpha_j \}. \tag{2}
\]

If we sort \( \alpha_1, \ldots, \alpha_K \) as \( \hat{\alpha}_1, \ldots, \hat{\alpha}_K \) such that \( \hat{\alpha}_1 \geq \hat{\alpha}_2 \geq \ldots \geq \hat{\alpha}_K \), (2) is equivalent to

\[
\min_{i,j \in [K], i \neq j} \beta_{ij} > 3\hat{\alpha}_1 + \hat{\alpha}_2. \tag{3}
\]

The size angle \( \alpha_k \) is a measure of perturbation in \( k \)-th circular cone and \( \beta_{ij}, i \neq j \) is a measure of distance between the \( i \)-th basis vector and the \( j \)-th basis vector. Thus, (2) is similar to the second idea in [14] (cf. Section I-B1), namely, that the largest perturbation of the rows of \( \mathbf{V} \) is bounded by a function of the smallest distance from a row of \( \mathbf{H} \) to the convex hull of all other rows. This assumption is realistic for datasets whose samples can be clustered into distinct types; for example, image datasets in which images either contain a distinct foreground (e.g., a face) embedded on a background, or they only comprise a background. See Figure 1 for an illustration of the geometric assumption in (2) and refer to Figure 1 in [16] for an illustration of the separability condition.

Now we discuss the relation between our geometric assumption and the separability and near-separability [14], [16] conditions that have appeared in the literature (and discussed in Section I). Consider a data matrix \( \mathbf{V} \) generated under the extreme case of our geometric assumption that all the size angles of the \( K \) circular cones are zero. Then every column of \( \mathbf{V} \) is a nonnegative multiple of a basis vector of a circular cone. This means that all the columns of \( \mathbf{V} \) can be represented as nonnegative linear combinations of \( K \) columns, i.e., the \( K \) basis vectors \( \mathbf{u}_1, \ldots, \mathbf{u}_K \). This can be considered as a special case of separability assumption. When the size angles are not all zero, our geometric assumption can be considered as a special case of the near-separability assumption.

In Lemma 1, we show that Algorithm 1, which has time complexity \( O(KFN) \), correctly clusters the columns of \( \mathbf{V} \) under the geometric assumption.

Lemma 1: Under the geometric assumption on \( \mathbf{V} \), if Algorithm 1 is applied to \( \mathbf{V} \), then the columns of \( \mathbf{V} \) are partitioned into \( K \) subsets, such that the data points in the same subset are generated from the same truncated circular cone.

Proof: We normalize \( \mathbf{V} \) to obtain \( \mathbf{V}' \), such that all the columns of \( \mathbf{V}' \) have unit \( \ell_2 \) norm. From the definition, we know if a data point is in a truncated circular cone, then the normalized data point is also in the truncated circular cone. Then for any two columns \( \mathbf{x}, \mathbf{y} \) of \( \mathbf{V}' \) that are in the same truncated circular cone \( C_k \cap \mathcal{P}, k \in [K] \), the largest possible angle between them is \( \min\{2\alpha_k, \pi/2\} \), and thus the distance \( \|\mathbf{x} - \mathbf{y}\|_2 \) between these two data points is not larger than \( \sqrt{2(1 - \cos(2\alpha_k))} \). On the other hand, for any two columns \( \mathbf{x}, \mathbf{y} \) that are in two truncated circular cones \( C_i \cap \mathcal{P}, C_j \cap \mathcal{P}, i \neq j \), the smallest possible angle between them is \( \beta_{ij} - \alpha_i - \alpha_j \), thus the smallest possible distance between them is \( \sqrt{2(1 - \cos(\beta_{ij} - \alpha_i - \alpha_j))} \). Then under the geometric assumption (2), the distance between any two unit data points in distinct truncated circular cones is larger than the distance between any two unit data points in the same truncated circular cone. Hence, Algorithm 1 returns the correct clusters.

Now we present the following two useful lemmas. Lemma 2 provides an upper bound for perturbations of singular values. Lemma 3 shows that we can directly obtain the best rank-one nonnegative matrix factorization from the best rank-one SVD.

Lemma 2 (Perturbation of singular values [28]): If \( \mathbf{A} \) and \( \mathbf{A} + \mathbf{E} \) are in \( \mathbb{R}^{F \times N} \), then

\[
\sum_{p=1}^{P} \left( \sigma_p(\mathbf{A} + \mathbf{E}) - \sigma_p(\mathbf{A}) \right)^2 \leq \|\mathbf{E}\|_F^2, \tag{5}
\]

where \( P = \min\{F, N\} \) and \( \sigma_p(\mathbf{A}) \) is the \( p \)-th largest singular value of \( \mathbf{A} \). In addition, we have

\[
|\sigma_p(\mathbf{A} + \mathbf{E}) - \sigma_p(\mathbf{A})| \leq \sigma_1(\mathbf{E}) = \|\mathbf{E}\|_2 \tag{6}
\]

for any \( p \in [P] \).
Then there is a pair of factor matrices $V, \Lambda$ for which the singular value decomposition of $A$ is

$$A = V \Lambda V^T$$

we can find the best rank-one approximate NMF of $A$ by solving

$$\min_{\sigma \geq 0} \|A - \sigma |V| V^T\|^2_F$$

**Theorem 4:** Suppose all the data points in data matrix $V \in \mathbb{R}^{F \times N}$ are drawn from $K$ truncated circular cones $C_1 \cap \mathcal{P}_1, \ldots, C_K \cap \mathcal{P}_K$, where $C_k := C(u_k, \alpha_k)$ for $k \in [K]$. Then there is a pair of factor matrices $W, \Lambda$ such that

$$\|V - W \Lambda^T\|^2_F \leq \max_{k \in [K]} \{\sin \alpha_k\}.$$

**Proof:** Define $\mathscr{K} := \{n \in [N] : v_n \in C \cap \mathcal{P}\}$ (if a data point is contained in more than one truncated circular cones, we arbitrarily assign any one it is contained in). Then $\mathscr{K}$ is a disjoint index sets and their union is $[N]$. Any two data points $V(:, j_1)$ and $V(:, j_2)$ are in the same circular cone if $j_1$ and $j_2$ are in the same index set. Let $V_k = V(:, \mathcal{K})$, and without loss of generality, suppose that $V_k \in \mathcal{C}$ for $k \in [K]$. For any $k \in [K]$ and any column $z$ of $V_k$, suppose the angle between $z$ and $u_k$ is $\beta$, we have $\beta \leq \alpha_k$ and $\theta := \|z\|_2 (\cos \beta) u_k + y$, with $\|y\|_2 = \|z\|_2 (\sin \beta) \leq \|z\|_2 (\sin \alpha_k)$. Thus $V_k$ can be written as the sum of a rank-one matrix $A_k$ and a perturbation matrix $E_k$. By Lemma 3, we can find the best rank-one approximate NMF of $V_k$ from the singular value decomposition of $V_k$. Suppose $w_k^* \in \mathbb{R}^{F \times 1}$ and $h_k^* \in \mathbb{R}^{N \times 1}$ solve the best rank-one approximate NMF. Let $S_k := (w_k^* h_k^*)^T$ be the best rank-one approximation matrix of $V_k$. Let $P_k = \min_{\mathcal{K}} |\mathcal{K}|$, then by Lemma 2, we have

$$\|V_k - S_k\|^2_F = \sum_{p=2}^P \sigma_p^2 (V_k) = \sum_{p=2}^P \sigma_p^2 (A_k + E_k) \leq \|E_k\|^2_F.$$
controlled by these size angles. Note that rank-one SVD can be implemented by the power method efficiently [28]. Recall that as mentioned in Section II-A, Theorem 5 is similar to the corresponding theorem for the near-separable case in [14] in terms of the geometric condition imposed.

**Theorem 5:** Under the geometric assumption given in Section II-A for generating \( V \in \mathbb{R}^{F \times N} \), Algorithm 2 outputs \( W^* \in \mathbb{R}^{F \times K}_+ \), \( H^* \in \mathbb{R}^{K \times N}_+ \), such that

\[
\frac{\|V - W^*H^*\|_{\text{F}}}{\|V\|_{\text{F}}} \leq \max_{k \in [K]} \{ \sin \alpha_k \}. \tag{17}
\]

**Proof:** From Lemma 1, under the geometric assumption in Section II-A, we can obtain a set of non-empty, pairwise disjoint index sets \( \mathcal{J}_1, \mathcal{J}_2, \ldots, \mathcal{J}_K \subseteq [N] \) such that their union is \([N]\) and two data points \( V(:,j_1) \) and \( V(:,j_2) \) are in the same circular cones if and only if \( j_1 \) and \( j_2 \) are in the same index set. Then from Theorem 4, we can obtain \( W^* \) and \( H^* \) with the same upper bound on the relative error.

IV. PROBABILISTIC THEOREMS

We now provide a tighter relative error bound by assuming a probabilistic model. For simplicity, we assume a straightforward and easy-to-implement statistical model for the sampling procedure. We first present the proof of the tighter relative error bound corresponding to the probabilistic model in Theorem 6 to follow, then we show that the upper bound for relative error is tight if we assume all the circular cones are contained in nonnegative orthant in Theorem 8.

We assume the following generating process for each column \( v \) of \( V \) in Theorem 6 to follow.

1. sample \( k \in [K] \) with equal probability \( 1/K \);
2. sample the squared length \( l \) from the exponential distribution\(^1\) \( \text{Exp}(\lambda_k) \) with parameter (inverse of the expectation) \( \lambda_k \);
3. uniformly sample a unit vector \( z \in C_k \) w.r.t. the angle between \( z \) and \( u_k \);\(^2\)
4. if \( z \notin \mathbb{R}^F_+ \), set all negative entries of \( z \) to zero, and rescale \( z \) to be a unit vector;

\(^1\) \( \text{Exp}(\lambda) \) is the function \( x \mapsto \lambda \exp(-\lambda x)1\{x \geq 0\} \)

\(^2\) This means we first uniformly sample an angle \( \beta \in [0, \alpha_k] \) and subsequently uniformly sample a vector \( z \) from the set \( \{x \in \mathbb{R}^F : \|x\|_2 = 1, x^T u_k = \cos \beta \} \)

5) let \( v = \sqrt{z} \);

**Theorem 6:** Suppose the \( K \) truncated circular cones \( C_k \cap \mathcal{P} \) with \( C_k := C(u_k, \alpha_k) \in \mathbb{R}^F \) for \( k \in [K] \) satisfy the geometric assumption given by (2). Let \( \lambda := (\lambda_1, \lambda_2, \ldots, \lambda_K) \in \mathbb{R}^{K}_+ \). We generate the columns of a data matrix \( V \in \mathbb{R}^{F \times N}_+ \) from the above generative process. Let \( f(\alpha) = \frac{1}{2} - \frac{\sin 2\alpha}{4\alpha} \), then for a small \( \epsilon > 0 \), with probability at least \( 1 - 8 \exp(-\xi N \epsilon^2) \), one has

\[
\frac{\|V - W^*H^*\|_{\text{F}}}{\|V\|_{\text{F}}} \leq \sqrt{\sum_{k=1}^{K} f(\alpha_k)/\lambda_k / \sum_{k=1}^{K} 1/\lambda_k} + \epsilon, \tag{22}
\]

where the constant \( \xi > 0 \) depends only on \( \lambda_k \) and \( f(\alpha_k) \) for all \( k \in [K] \).

**Remark 1:** The assumption in Step 1 in the generating process that the data points are generated from \( K \) circular cones with equal probability can be easily generalized to unequal probabilities. The assumption in Step 2 that the square of the length of a data point is sampled from an exponential distribution can be easily extended to any nonnegative sub-exponential distribution (cf. Definition 2 below), or equivalently, the length of a data point is sampled from a nonnegative sub-gaussian distribution (cf. Definition 3 in Appendix A).

The relative error bound produced by Theorem 6 is better than that of Theorem 5, i.e., the former is more conservative. This can be seen from (26) to follow, or from the inequality \( \alpha \leq \tan \alpha \) for \( \alpha \in [0, \pi/2] \). We also observe this in the experiments in Section VI-A1.

Before proving Theorem 6, we define sub-exponential random variables and present a useful lemma.

**Definition 2:** A sub-exponential random variable \( X \) is one that satisfies one of the following equivalent properties

1. **Tails:** \( \mathbb{P}(\|X\| > t) \leq \exp(1 - t/K_1) \) for all \( t \geq 0 \);
2. **Moments:** \( \mathbb{E}|X|^p \leq K_2 p! \) for all \( p \geq 1 \);
3. **Sub-exponential norm of \( X \)**, denoted \( \|X\|_{\psi_1} \), is defined to be

\[
\|X\|_{\psi_1} := \sup_{p \geq 1} p^{-1} (\mathbb{E}|X|^p)^{1/p}. \tag{23}
\]

**Lemma 7:** (Bernstein-type inequality) [30] Let \( X_1, \ldots, X_N \) be independent sub-exponential random variables with zero expectations, and \( M = \max_i \|X_i\|_{\psi_1} \). Then for every \( \epsilon \geq 0 \), we have

\[
\mathbb{P}\left( \left| \sum_{i=1}^{N} X_i \right| \geq \epsilon N \right) \leq 2 \exp\left[ -c \cdot \min \left( \frac{\epsilon^2}{M^2}, \frac{\epsilon}{M} \right) N \right], \tag{24}
\]

where \( c > 0 \) is an absolute constant.

Theorem 6 is proved by combining the large deviation bound in Lemma 7 with the deterministic bound on the relative error in Theorem 5.

**Proof of Theorem 6:** From (9) and (10) in the proof of Theorem 5, to obtain an upper bound for the square of the relative error, we consider the following random variable

\[
D_N := \frac{\sum_{n=1}^{N} L_n^2 \sin^2 B_n}{\sum_{n=1}^{N} L_n^2}, \tag{25}
\]
where $L_n$ is the random variable corresponding to the length of the $n$-th point, and $B_n$ is the random variable corresponding to the angle between the $n$-th point and $u_k$ for some $k \in [K]$ such that the point is in $C_k \cap P$. We first consider estimating the above random variable with the assumption that all the data points are generated from a single truncated circular cone $C \cap P$ with $C := C(u, \alpha)$ (i.e., assume $K = 1$), and the square of lengths are generated according to the exponential distribution $\text{Exp}(\lambda)$. Because we assume each angle $\beta_n$ for $n \in [N]$ is sampled from a uniform distribution on $[0, \alpha]$, the expectation of $\sin^2 B_n$ is

$$
E[\sin^2 B_n] = \int_0^{\alpha} \frac{1}{\alpha} \sin^2 \beta \, d\beta = \frac{1}{2} - \frac{\sin 2\alpha}{4\alpha} = f(\alpha). \quad (26)
$$

Here we only need to consider vectors $z \in \mathbb{R}_+^r$ whose angles with $u$ are not larger than $\alpha$. Otherwise, we have $E[\sin^2 B_n] \leq f(\alpha)$. Our probabilistic upper bound also holds in this case.

Since the length and the angle are independent, we have

$$
E[D_N] = E[E[D_N|L_1, \ldots, L_N]] = f(\alpha), \quad (27)
$$

and we also have

$$
E[L_n^2 \sin^2 B_n] = E[L_n^2] E[\sin^2 B_n] = \frac{f(\alpha)}{\lambda}. \quad (28)
$$

Define $X_n := L_n^2$ for all $n \in [N]$. Let

$$
H_n := \sum_{n=1}^{N} X_n, \quad \text{and} \quad G_n := \sum_{n=1}^{N} X_n \sin^2 B_n. \quad (29)
$$

We have for all $n \in [N],$

$$
E[X_n^p] = \lambda^{-p} \Gamma(p + 1) \leq \lambda^{-p} p^p, \quad \forall p \geq 1, \quad (30)
$$

where $\Gamma(\cdot)$ is the gamma function. Thus $\|X_n\|_{\psi_1} \leq \lambda^{-1},$ and $X_n$ is sub-exponential. By the triangle inequality, we have $\|X_n - EX_n\|_{\psi_1} \leq \|X_n\|_{\psi_1} + \|EX_n\|_{\psi_1} \leq 2\|X_n\|_{\psi_1}$. Hence, by Lemma 7, for all $\epsilon > 0$, we have (24) where $M$ can be taken as $M = 2/\lambda$. Because

$$
\left(\mathbb{E}[\left(X_n \sin^2 B_n\right)^p]\right)^{1/p} \leq \lambda^{-1} p \sin^2 \alpha \leq \lambda^{-1} p, \quad (31)
$$

we have a similar large deviation result for $G_N$. On the other hand, for all $\epsilon > 0$

$$
P(|D_N - f(\alpha)| \geq \epsilon) = P\left(\frac{G_N}{H_N} - f(\alpha) \geq \epsilon\right) \leq P\left(|\lambda G_N - f(\alpha)| \geq \frac{\epsilon}{2}\right) + P\left(\frac{G_N}{H_N} - \lambda G_N \geq \frac{\epsilon}{2}\right). \quad (32)
$$

For the second term, by fixing small constants $\delta_1, \delta_2 > 0$, we have

$$
P\left(\frac{G_N}{H_N} - \lambda G_N \geq \frac{\epsilon}{2}\right) = P\left(\frac{1 - \lambda H_N}{H_N} G_N \geq \frac{\epsilon}{2}\right) \leq P\left(\frac{1 - \lambda H_N}{H_N} G_N \geq \frac{\epsilon}{2}, H_N \geq \frac{1}{\lambda - \delta_1}, \frac{G_N}{\lambda} + \delta_2\right) + P\left(H_N < \frac{1}{\lambda - \delta_1}\right). \quad (33)
$$

Combining the large deviation bounds for $H_N$ and $G_N$ in (34) with the above inequalities, if we set $\delta_1 = \delta_2 = \epsilon$ and take $\epsilon$ sufficiently small,

$$
P(|D_N - f(\alpha)| \geq \epsilon) \leq 8 \exp(-\xi N \epsilon^2), \quad (36)
$$

where $\xi$ is a positive constant depending on $\lambda$ and $f(\alpha)$.

Now we turn to the general case in which $K \in \mathbb{N}$. We have

$$
E[X_n] = \frac{\sum_{k=1}^{K} 1/\lambda_k}{K}, \quad (37)
$$

$$
E[X_n \sin^2 B_n] = \frac{\sum_{k=1}^{K} f(\alpha_k)/\lambda_k}{K}, \quad (38)
$$

and for all $p \geq 1$,

$$
\left(\mathbb{E}[X_n^p]\right)^{1/p} = \left(\frac{\sum_{k=1}^{K} \lambda_k^p \Gamma(p + 1)}{K}\right)^{1/p} \leq \frac{p}{\min_k \lambda_k}. \quad (39)
$$

Similar to (36), we have

$$
P\left(|D_N - \frac{\sum_{k=1}^{K} f(\alpha_k/\lambda_k)}{\sum_{k=1}^{K} 1/\lambda_k}| \geq \epsilon\right) \leq 8 \exp\left(-\xi N \epsilon^2\right), \quad (40)
$$

and thus, if we let $\Delta := \frac{\sum_{k=1}^{K} f(\alpha_k)/\lambda_k}{\sum_{k=1}^{K} 1/\lambda_k}$, we have

$$
P\left(\sqrt{D_N - \Delta} \leq \epsilon\right) \geq P\left(|D_N - \Delta^2| \leq \Delta \epsilon\right) \geq 1 - 8 \exp\left(-\xi N \Delta^2 \epsilon^2\right). \quad (41)
$$

This completes the proof of (22).

Furthermore, if the $K$ circular cones $C_1, \ldots, C_K$ are contained in the nonnegative orthant $P$, we do not need to project the data points not in $P$ onto $P$. Then we can prove that the upper bound in Theorem 6 is asymptotically tight, i.e.,

$$
\frac{\|V - W^* H^*\|_F}{\|V\|_F} \leq \frac{\sum_{k=1}^{K} f(\alpha_k)/\lambda_k}{\sum_{k=1}^{K} 1/\lambda_k}, \quad \text{as } N \to \infty. \quad (43)
$$

**Theorem 8:** Suppose the data points of $V \in \mathbb{R}^{F \times N}_+$ are generated as given in Theorem 6 with all the circular cones being contained in the nonnegative orthant, then Algorithm 2 produces $W^* \in \mathbb{R}^{F \times K}$ and $H^* \in \mathbb{R}^{K \times N}$ with the property that for any $\epsilon \in (0, 1)$ and $t \geq 1$, if $N \geq c(t/\epsilon)^2 F$, then with probability at least $1 - 6K \exp(-t^2F)$ one has

$$
\frac{\|V - W^* H^*\|_F}{\|V\|_F} \leq \frac{\sum_{k=1}^{K} f(\alpha_k)/\lambda_k}{\sum_{k=1}^{K} 1/\lambda_k} \leq c \epsilon \quad (44)
$$

where $c$ is a constant depending on $K$ and $\alpha_k, \lambda_k$ for $k \in [K]$.

**Proof:** Since the proof of Theorem 8 is somewhat similar to that of Theorem 6, we defer it to Appendix A.

**V. AUTOMATICALLY DETERMINING $K$**

Automatically determining the latent dimensionality $K$ is an important problem in NMF. Unfortunately, the usual and popular approach for determining the latent dimensionality of nonnegative data matrices based on Bayesian automatic relevance determination by Tan and Févotte [31] does not work well for data matrices generated under the geometric assumption given in Section II-A. This is because in [31], $W$ and $H$ are assumed to be generated from the same distribution. Under the geometric assumption, $V$ has well clustered columns and the corresponding coefficient matrix $H$ can be approximated by a clustering membership indicator.
matrix with columns that are 1-sparse (i.e., only contains one non-zero entry). Thus, $W$ and $H$ have very different statistics. While there are many approaches [32]–[34] to learn the number of clusters in clustering problems, most methods lack strong theoretical guarantees.

By assuming the generative procedure for $V$ proposed in Theorem 6, we consider a simple approach for determining $K$ based on the maximum of the ratios between adjacent singular values. We provide a theoretical result for the correctness of Theorem 6, we consider a simple approach for determining $K$ in the nonnegative orthant $\mathcal{P}$ (cf. Section VI-A2) that if $V$ satisfies the geometric assumption (even approximately), the results are superior compared to the scenario when the assumption is significantly violated.

Remark 3: We may replace the assumption that the circular cones are contained in the nonnegative orthant by removing Step 4 in the generating process (projection onto $\mathcal{P}$) in the generative procedure in Theorem 6. Because we are concerned with finding the number of clusters (or circular cones) rather than determining the true latent dimensionality of an NMF problem (cf. [31]), we can discard the nonnegativity constraint. The number of clusters serves as a proxy for the latent dimensionality of NMF.

VI. NUMERICAL EXPERIMENTS

A. Experiments on Synthetic Data

To verify the correctness of our bounds, to observe the computational efficiency of the proposed algorithm, and to check if the procedure for estimating $K$ is effective, we first perform numerical simulations on synthetic datasets. All the experiments were executed on a Windows machine whose processor is an Intel(R) Core(TM) i5-3570, the CPU speed is 3.40 GHz, and the installed memory (RAM) is 8.00 GB. The Matlab version is 7.11.0.584 (R2010b). The Matlab codes for running the experiments can be found at https://github.com/zhaoqiangliu/crl1-nmf.

1) Comparison of Relative Errors and Running Times:

To generate the columns of $V$, given an integer $k \in [K]$ and an angle $\beta \in [0, \alpha_k]$, we uniformly sample a vector $z$ from $\{x : x^T u_k = \cos \beta\}$, i.e., $z$ is a unit vector such that the angle between $z$ and $u_k$ is $\beta$. To achieve this, note that if $\mathbf{u}_k = \mathbf{e}_f, f \in [F]$ ($\mathbf{e}_f$ is the vector with only the $f$-th entry being 1), this uniform sampling can easily be achieved. For example, we can take $\mathbf{x} = (\cos \beta) \mathbf{e}_f + (\sin \beta) \mathbf{y}$, where $y(f) = 0$, $y(i) = s(i)/\sqrt{\sum_{j \neq f} s(j)^2}, i \neq f$, and $s(i) \sim \mathcal{N}(0,1), i \neq f$. We can then use a Householder transformation [36] to map the unit vector generated from the circular cone with basis vector $\mathbf{e}_f$ to the unit vector generated from the circular cone with basis vector $\mathbf{u}_k$. The corresponding Householder transformation matrix is (if $\mathbf{u}_k = \mathbf{e}_f$, $\mathbf{P}_k$ is set to be the identity matrix $I$)

$$
\mathbf{P}_k = \mathbf{I} - 2\mathbf{z}_k \mathbf{z}_k^T, \quad \mathbf{z}_k = \frac{\mathbf{e}_f - \mathbf{u}_k}{||\mathbf{e}_f - \mathbf{u}_k||_2}.
$$

In this set of experiments, we set the size angles $\alpha$ to be the same for all the circular cones. The angle between any two basis vectors is set to be $4\alpha + \Delta \alpha$ where $\Delta \alpha := 0.01$. The parameter for the exponential distribution $\lambda := 1/(1 : K)$. We increase $N$ from $10^2$ to $10^4$ logarithmically. We fix the parameters $F = 1600, K = 40$ and $\alpha = 0.2$ or 0.3. The results shown in Figure 2. In the left plot of Figure 2, we compare the relative errors of Algorithm 2 (crl1-nmf) with
the derived relative error bounds. In the right plot, we compare the relative errors of our algorithm with the relative errors of three classical algorithms: (i) the multiplicative update algorithm [3] (mult); (ii) the alternating nonnegative least-squares algorithm with block-pivoting (nnlsb), which is reported to be one of the best alternating nonnegative least-squares-type algorithm for NMF in terms of both running time and approximation error [6]; (iii) and the hierarchical alternating least squares algorithm [8] (hals). In contrast to these three algorithms, our algorithm is not iterative. The iteration numbers for mult and hals are set to 100, while the iteration number for nnlsb is set to 20, which is sufficient (in our experiments) for approximate convergence. For statistical soundness of the results of the plots on the left, 50 data matrices \( V \in \mathbb{R}^{50 \times 10000} \) are independently generated and for each data matrix \( V \), we run our algorithm for 20 runs. For the plots on the right, 10 data matrices \( V \) are independently generated and all the algorithms are run for 10 times for each \( V \). We also compare the running time for these algorithms when they first achieve the approximation error smaller than or equal the approximation error of Algorithm 2. The running times are shown in Table I. Because the running times for \( \alpha = 0.2 \) and \( \alpha = 0.3 \) are similar, we only present the running times for the former.

From Figure 2, we observe that the relative errors obtained from Algorithm 2 are smaller than the theoretical relative error bounds. When \( \alpha = 0.2 \), the relative error of Algorithm 2 appears to converge to the probabilistic relative error bound as \( N \) becomes large, but when \( \alpha = 0.3 \), there is a gap between the relative error and the probabilistic relative error bound. From Theorems 6 and 8, we know that this difference is due to the projection of the cones to the nonnegative orthant. If there is no projection (this may violate the nonnegative constraint), the probabilistic relative error bound is tight as \( N \) tends to infinity. We conclude that when the size angle \( \alpha \) is large, the projection step causes a larger gap between the relative error and the probabilistic relative error bound. We observe from Figure 2 that there are large oscillations for mult. Other algorithms achieve similar approximation errors. Table I shows that classical NMF algorithms require significantly more time (at least an order of magnitude for large \( N \)) to achieve the same relative error compared to our algorithm.

2) Automatically Determining \( K \): We now verify the efficacy and the robustness of the proposed method in (45) for automatically determining the correct number of circular cones. We generated the data matrix \( \hat{V} := [V + \delta E]_+ \), where each entry of \( E \) is sampled i.i.d. from the standard normal distribution, \( \delta > 0 \) corresponds to the noise magnitude, and \( [\cdot]_+ \) represents the projection to nonnegative orthant operator. We generated the nominal/noiseless data matrix \( V \) by setting

\[ \alpha = 0.3 \text{, the true number of circular cones } K = 40 \text{, and other parameters similarly to the procedure in Section VI-A1.} \]

\[ \text{The noise magnitude } \delta \text{ is set to be either 0.1 or 0.5; the former simulates a relatively clean setting in which the geometric assumption is approximately satisfied, while in the latter, } V \text{ is far from a matrix that satisfies the geometric assumption, i.e., a very noisy scenario. We generated 1000 perturbed data matrices } V \text{ independently. From Figure 3 in which the true } K = 40 \text{, we observe that, as expected, the method in (45) works well if the noise level is small. Somewhat surprisingly, it also works well even when the noise level is relatively high (e.g., } \delta = 0.5 \text{ if the number of data points } N \text{ is also commensurately large (e.g., } N \geq 5 \times 10^3).} \]

### B. Experiments on Real Datasets

1) Initialization Performance in Terms of the Relative Error: Because real datasets do not, in general, strictly satisfy the geometric assumption, our algorithm crl-nmf, does not achieve as low a relative error compared to other NMF
algorithms. However, similar to the popular spherical k-means (spkm; we use 10 iterations to produce its initial left factor matrix $W$) algorithm [22], our algorithm may be used as initialization method for NMF. In this section, we compare crl-nmf to other classical and popular initialization approaches for NMF. These include random initialization (rand), spkm, and the nndsvd initialization method [23] (nndsvd). We empirically show that our algorithm, when used as an initializer, achieves the best performance when combined with classical NMF algorithms. The specifications of the real datasets and the running times for the initialization methods are presented in Tables II and III respectively.

We use mult, nnlsb, and hals as the classical NMF algorithms that are combined with the initialization approaches. Note that for nnlsb, we only need to initialize the left factor matrix $W$. This is because the initial $H$ can be obtained from initial $W$ using [6, Algorithm 2]. Also note that the pair $(W^*, H^*)$ produced by Algorithm 2 is a fixed point for mult (see Lemma 15 in Appendix C), so we use a small perturbation of $H^*$ as an initialization for the right factor matrix. For spkm, similarly to [22], [23], we initialize the right factor matrix randomly. In addition, to ensure a fair comparison between these initialization approaches, we need to shift the iteration numbers appropriately, i.e., the initialization method that takes a longer time should start with a commensurately smaller iteration number when combined one of the three classical NMF algorithms. Table IV reports the number of shifts. Note that unlike mult and hals, the running times for different iterations of nnlsb can be significantly different. We observe that for most datasets, when run for the same number of iterations, random initialization and nndsvd initialization not only result in larger relative errors, but they also take a much longer time than spkm and our initialization approach. Because initialization methods can also affect the running time of each iteration of nnlsb significantly, we do not report shifts for initialization approaches when combined with nnlsb. Table V reports running times that various algorithms first achieve a fixed relative error $\epsilon > 0$ for various initialization methods when combined with nnlsb. Our proposed algorithm is clearly superior.

We observe from Figure 4 that our algorithm almost always outperforms all other initialization approaches in terms of convergence speed and/or the final relative error when combined with classical NMF algorithms (except that nndsvd+hals performs the best for PaviaU). In addition, we present the results from the Georgia Tech image dataset. For ease of illustration, we only display the results for 3 individuals (there are images for 50 individuals in total) for the various initialization methods combined with mult. Several images of these 3 individuals are presented in Figure 5. The basis images produced at the 20th iteration are presented in Figure 6 (more basis images obtained at other iteration numbers are presented in the supplementary material). We observe from the basis images in Figure 6 that our initialization method is clearly superior to rand and nndsvd. In the supplementary material, we additionally present an illustration of Table V as a figure where the horizontal and vertical axes are the running times (instead of number of iterations) and the relative errors respectively. These additional plots substantiate our conclusion that Algorithm 2 serves as a good initializer for various other NMF algorithms.

2) Intuition for the Advantages of crl-nmf over spkm as an Initializer for NMF Algorithms: From Figure 4, we see that the difference between the results obtained from using

spkm as initialization method and the corresponding results obtained from using our initialization approach appears to be rather insignificant. However, from Table V, which reports the running time to first achieve specified relative errors $\epsilon > 0$ for the initialization methods combined with nnlsb (note that nnlsb only needs to use the initial left factor matrix, and thus we can compare the initial estimated basis vectors obtained by spkm and cr1-nmf directly), we see that our initialization approach is clearly faster than spkm.

In addition, consider the scenario where there are duplicate or near-duplicate samples. Concretely, assume the data matrix $V := \begin{bmatrix} 1 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \in \mathbb{R}^{2 \times 3}$ and $K = 1$. Then the left factor matrix produced by rank-one NMF is $w = [1; 0]$ and the normalized mean vector (centroid for spkm) is $\bar{u} := \frac{1}{\sqrt{3} \sqrt{5}}$. The approximation error w.r.t. $w$ is $\|V - ww^T V\|_F = 1$, while the approximation error w.r.t. $\bar{u}$ is $\|V - \bar{u}\bar{u}^T V\|_F \approx 1.0954$. Note that spkm is more constrained since it implicitly outputs a binary right factor matrix $H \in \{0, 1\}^{K \times N}$ while rank-one NMF (cf. Lemma 3) does not impose this stringent requirement. Hence cr1-nmf generally leads to a smaller relative error compared to spkm.

3) Initialization Performance in Terms of Clustering: We now compare clustering performances using various initialization methods. To obtain a comprehensive evaluation, we use three widely-used evaluation metrics, namely, the normalized mutual information [37] (nmi), the Dice coefficient [38] (Dice) and the purity [39], [40]. The clustering results for the CK and tr11$^7$ datasets are shown in Tables VI and VII respectively. Clustering results for other datasets are shown in the supplementary material (for space considerations). We run the standard k-means and spkm clustering algorithms for at most 1000 iterations and terminate the algorithm if the cluster memberships do not change. All the classical NMF algorithms are terminated if the variation of the product of factor matrices is small over 10 iterations. Note that nnlsbd is a deterministic initialization method, so its clustering results are the same across different runs. We observe from Tables VI and VII and those in the supplementary material that our initialization approach almost always outperforms all others (under all the three evaluation metrics).

VII. CONCLUSION AND FUTURE WORK

A. Summary of Contributions

We proposed a new geometric assumption for the purpose of performing NMF. In contrast to the separability condition [13], [14], [16], under our geometric assumption, we are able to prove several novel deterministic and probabilistic results concerning the relative errors of learning the factor matrices. We are also able to provide a theoretically-grounded method of

![Figure 4. The first to fourth rows are the numerical results for CK, faces94, Georgia Tech, and PaviaU datasets respectively.](image)

![Figure 5. Images of 3 individuals in Georgia Tech dataset.](image)
choosing the number of clusters (i.e., the number of circular cones) $K$. We showed experimentally on synthetic datasets that satisfy the geometric assumption that our algorithm performs exceedingly well in terms of accuracy and speed. Our method also serves a fast and effective initializer for running NMF on real datasets. Finally, it outperforms other competing methods on various clustering tasks.

### B. Future Work and Open Problems

We plan to explore the following extensions.

1) First, we hope to prove theoretical guarantees for the scenario when $V$ only satisfies an approximate version of the geometric assumption, i.e., we only have access to $V := |V + \delta E|$ (cf. Section VI-A2) where $\delta \approx 0$.

2) Second, here we focused on upper bounds on the relative error. To assess the tightness of these bounds, we hope to prove minimax lower bounds on the relative error similarly to Jung et al. [41].

3) Third, as mentioned in Section I-A1, our geometric assumption in (2) can be considered as a special case of the near-separability assumption for NMF [13]. To the best of our knowledge, there is no theoretical guarantee for the relative error under the near-separability assumption.

4) For large-scale data, it is often desirable to perform NMF in an online fashion [42], [43], i.e., each data point $v_n$ arrives in a sequential manner. We would like to develop online versions of the algorithm herein.

5) It would be fruitful to leverage the theoretical results for $k$-means++ [44] to provide guarantees for a probabilistic version of our initialization method. Note that our method is deterministic while $k$-means++ is probabilistic, so a probabilistic variant of Algorithm 2 may have to be developed for fair comparisons with $k$-means++.

6) We may also extend our Theorem 9 to near-separable data matrices, possibly with additional assumptions.

### APPENDIX A

#### PROOF OF THEOREM 8

To prove Theorem 8, we first provide a few definitions and lemmas. Consider the following condition that ensures that the circular cone $C(u, \alpha)$ is entirely contained in the non-negative orthant $\mathcal{P}$.

**Lemma 10:** If $u = (u(1), u(2), \ldots, u(F))$ is a positive unit vector and $\alpha > 0$ satisfies

$$\alpha \leq \arccos \sqrt{1 - \frac{u_{\min}^2}{u_{\max}^2}},$$

where \( u_{\text{min}} = \min_{f} u(f) \), then \( C(u, \alpha) \leq \mathcal{P} \).

Proof of Lemma 10: Because any nonnegative vector \( x \) is spanned by basis vectors \( e_1, e_2, \ldots, e_F \), given a positive unit vector \( u \), to find the largest size angle, we only need to consider the angle between \( u \) and \( e_f, f \in [F] \). Take any \( f \in [F] \), if the angle \( \beta \) between \( u \) and \( e_f \) is not larger than \( \pi/4 \), we can obtain the unit vector symmetric to \( e_f \) w.r.t. \( u \) in the plane spanned by \( u \) and \( e_f \) is also nonnegative. In fact, the vector is \( 2 \cos(\beta)u - e_f \). Because \( u(f) = \cos(\beta) \) and \( \beta \leq \pi/4 \), we have \( 2 \cos^2 \beta \geq 1 \) and the vector is nonnegative. If \( \beta > \pi/4 \), i.e., \( u(f) < 1/\sqrt{2} \), we can take the extreme nonnegative unit vector \( z \) in the span of \( u \) and \( e_f \), i.e.,

\[
z = \frac{u - u(f)e_f}{\|u - u(f)e_f\|_2},
\]

and it is easy to see \( u^Tz = \sqrt{1 - u(f)^2} \). Hence the angle between \( z \) and \( u \) is \( \pi/2 - \beta < \pi/4 \). Therefore, the largest size angle \( \alpha_{e_f} \) w.r.t. \( e_f \) is

\[
\alpha_{e_f} := \begin{cases}
\arccos u(f), & \text{if } u(f) \geq 1/\sqrt{2} \\
\arccos \sqrt{1-u(f)^2}, & \text{if } u(f) < 1/\sqrt{2}
\end{cases}
\]

or equivalently, \( \alpha_{e_f} = \min\{\arccos u(f), \arccos \sqrt{1-u(f)^2}\} \).

Thus, the largest size angle corresponding to \( u \) is

\[
\min_f \{ \min\{\arccos u(f), \arccos \sqrt{1-u(f)^2}\} \}.
\]

Let \( u_{\text{max}} := \max_f u(f) \) and \( u_{\text{min}} := \min_f u(f) \). Then the largest size angle corresponding to \( u \) is

\[
\min \{ u_{\text{max}}, \arccos \sqrt{1-u_{\text{min}}^2} \}. \tag{52}
\]

Because \( u_{\text{max}}^2 + u_{\text{min}}^2 \leq 1 \) for \( F > 1 \), the expression in (52) equals \( \arccos \sqrt{1-u_{\text{min}}^2} \) and this completes the proof. \hfill \Box

Lemma 11: Define \( f(\beta) := \frac{1}{2} - \sin(2\beta/4) \) and \( g(\beta) := \frac{1}{2} + \frac{\sin(2\beta)}{4} \) for \( \beta \in \left(0, \frac{\pi}{2}\right) \). Let \( e_f, f \in [F] \) be the unit vector with only the \( f \)-th entry being 1, and \( C \) be the circulant matrix with basis vector \( u = e_f \), size angle being \( \alpha \), and the inverse expectation parameter for the exponential distribution being \( \lambda \). Then if the columns of the data matrix \( V \in \mathbb{R}^{F \times N} \) are generated as in Theorem 6 from \( C \) (\( K = 1 \)) and with no projection to the nonnegative orthonal (Step 4 in the generating process), we have

\[
E \left( \frac{V V^T}{N} \right) = D_f \lambda \tag{53}
\]

where \( D_f \) is a diagonal matrix with the \( f \)-th diagonal entry being \( g(\alpha) \) and other diagonal entries being \( f(\alpha)/(F - 1) \).

Proof of Lemma 11: Each column \( v_n, n \in [N] \) can be generated as follows: First, uniformly sample a \( \beta_n \in [0, \alpha] \) and sample a positive scalar \( \lambda_n \) from the exponential distribution \( \text{Exp}(\lambda) \), then we can write \( v_n = \sqrt{\lambda_n} \left[ \cos \beta_n e_f + \sin \beta_n y_n \right] \), where \( y_n \) can be generated from sampling \( y_n(1), \ldots, y_n(f-1), y_n(f+1), \ldots, y_n(F) \) from the standard normal distribution \( N(0, 1) \), and setting \( y_n(j) = y_n(j)/\sqrt{\sum_{i \neq f} y_n(i)^2} \), \( j \neq f \), \( y_n(f) = 0 \). Then

\[
E[|v_n(f)v_n(f)|^2] = E[|f_n((\cos^2 \beta)e_f(f_1)e_f(f_2) + (\sin^2 \beta)y_n(f_1)y_n(f_2))|] \tag{54}
\]

\[
= \left\{ \begin{array}{ll}
0, & f_1 \neq f_2, \\
g(\alpha)/\lambda, & f_1 = f_2 = f, \\
f(\alpha)/(((F-1)\lambda), & f_1 \neq f_2.
\end{array} \right. \tag{55}
\]

where \( e_f(f_1) = 1 \{ f = f_1 \} \) is the \( f \)-th entry of the vector \( e_f \). Thus \( E[V V^T/N] = E[v_n v_n^T] = D_f \lambda \).

Definition 3: A sub-gaussian random variable \( X \) is one that satisfies one of the following equivalent properties:

1. Tails: \( \mathbb{P}(|X| > t) \leq \exp \left(-t^2/K_2^2\right) \) for all \( t \geq 0 \);
2. Moments: \( E[|X|^p]^{1/p} \leq K_2 \sqrt{p} \) for all \( p \geq 1 \);
3. \( E[\exp(X^2/K_2^2)] \leq e \);

where \( K_i, i = 1, 2, 3 \) are positive constants. The sub-gaussian norm of \( X \), denoted \( \|X\|_{\Psi_2} \), is defined to be

\[
\|X\|_{\Psi_2} := \sup_{p \geq 1} p^{-1/2} (E|X|^p)^{1/p}. \tag{56}
\]

A random vector \( X \in \mathbb{R}^F \) is called sub-gaussian if \( X^T X \) is a sub-gaussian random variable for any constant vector \( x \in \mathbb{R}^F \). The sub-gaussian norm of \( X \) is defined as

\[
\|X\|_{\Psi_2} := \sup_{\|x\|_2 = 1} \|X^T x\|_{\Psi_2}. \tag{57}
\]

Lemma 12: A random variable \( X \) is sub-gaussian if and only if \( X^2 \) is sub-exponential. Moreover, it holds that

\[
\|X\|_{\Psi_2} \leq \|X\|_{\Psi_1} \leq 2 \|X\|_{\Psi_2}. \tag{58}
\]

See Vershynin [30] for the proof.

Lemma 13 (Covariance estimation of sub-gaussian distributions [30]): Consider a sub-gaussian distribution \( P \in \mathbb{R}^F \) with covariance matrix \( \Sigma \). Let \( \epsilon \in (0,1) \) and \( t \geq 1 \). If \( N \geq c(t\epsilon)^2 F \), then with probability at least \( 1 - 2 \exp(-t^2 F) \),

\[
\|\Sigma_N - \Sigma\|_2 \leq \epsilon, \tag{59}
\]

where \( \| \cdot \|_2 := \sigma(\cdot) \) is the spectral norm, \( \Sigma_N := \sum_{n=1}^N X_n X_n^T/N \) is the empirical covariance matrix, and \( X_n, n \in [N] \) are independent samples from \( P \). The constant \( c = c_g \) depends only on the sub-gaussian norm \( g = \|X\|_{\Psi_2} \) of the random vector \( X \) sampled from this distribution.

Proof of Theorem 8: Similar to Theorem 5, we have

\[
\frac{\|V - W^* H^*\|^2}{\|V\|^2} = \frac{\sum_{k=1}^K \|V_k - w_k^* b_k^T\|^2_F}{\sum_{k=1}^K \|V_k\|^2_F} \tag{60}
\]

\[
= \frac{\sum_{k=1}^K \left( \|V_k\|^2_F - \sigma^2_k(V_k) \right)}{\sum_{k=1}^K \|V_k\|^2_F} \tag{61}
\]

\[
= 1 - \frac{\sum_{k=1}^K \sigma^2_k(V_k)}{\sum_{k=1}^K \|V_k\|^2_F}. \tag{62}
\]

Take any \( k \in [K] \) and consider \( \sigma^2_k(V_k) \). Define the index \( f_k := \arg\min_{f \in [F]} u_k \) and the orthogonal matrix \( P_k \) as in (47). The columns of \( V_k \) can be considered as Householder transformations of the data points generated from the circular cone \( C_{f_k} := C(e_{f_k}, \alpha_k) \) (the circular cone with basis vector \( e_{f_k} \) and size angle \( \alpha_k \), i.e., \( V_k = P_k X_k \), where \( X_k \) contains...
the corresponding data points in $C_0^0$. In addition, denoting $N_k$ as the number of data points in $V_k$, we have
\[
\frac{\sigma_k^2(V_k)}{N_k} = \lambda_{\max} \left( \frac{V_k V_k^T}{N_k} \right)
\]
where $\lambda_{\max} (V_k V_k^T/N_k)$ represents the largest eigenvalue of $V_k V_k^T/N_k$. Take any $v \in V_k$. Note that $v$ can be written as $v = P_k x$ with $x$ being generated from $C_0^0$. Now, for all unit vectors $z \in \mathbb{R}^F$, we have
\[
\|v\|_2 = \|P_k x\|_2 = \|x\|_2
\]
\[
\geq \sup_{\|x\|_2 = 1} \sup_{p \geq 1} p^{-1/2} \left( \mathbb{E} \left( \|x^T z|^p \right) \right)^{1/p}
\]
\[
\leq \sup_{p \geq 1} p^{-1/2} \mathbb{E} \left( \|x\|_2^p \right)^{1/p}
\]
\[
\geq \sqrt{\|\|x\|_2^2 \|_1} \leq 1 / \sqrt{\lambda_k}.
\]
That is, all columns are sampled from a sub-gaussian distribution. By Lemma 11,
\[
\mathbb{E} (v v^T) = \mathbb{E} (P_k x x^T P_k^T) = P_k D_k P_k^T / \lambda_k.
\]
By Lemma 13, we have for $\epsilon \in (0, 1), \xi \geq 1$ and if $N_k \geq \xi_k (t/\epsilon)^2 F$ ($\xi_k$ is a positive constant depending on $\lambda_k$), with probability at least $1 - 2 \exp(-t^2 F)$,
\[
\|v v^T - E(v v^T)\|_2 \leq \epsilon.
\]
where the final inequality follows from Lemma 2. Because $\lambda_{\max} (v v^T) = g(\alpha_k) / \lambda_k$, we can obtain that with probability at least $1 - 4K \exp(-t^2 F)$,
\[
\sum_{k=1}^{K} \frac{\sigma_k^2(V_k)}{N_k} = \sum_{k=1}^{K} \frac{g(\alpha_k)}{K \lambda_k}
\]
\[
\leq 2K \epsilon.
\]
where the final inequality follows from the triangle inequality and (69). From the proof of Theorem 6, we know that with probability at least $1 - 2 \exp(-c_1 N \epsilon^2)$, we have
\[
\left( \frac{\|V\|_F^2}{N} - \sum_{k=1}^{K} \frac{1}{\lambda_k} \right) \leq \epsilon.
\]
Taking $N$ to be sufficiently large such that $t^2 F \leq c_1 N \epsilon^2$, we have with probability at least $1 - 6K \exp(-t^2 F)$,
\[
\sum_{k=1}^{K} g(\alpha_k) / \lambda_k - c_2 \epsilon \leq \sum_{k=1}^{K} \frac{\sigma_k^2(V_k)}{N_k} \leq \sum_{k=1}^{K} \frac{g(\alpha_k)}{K \lambda_k} + c_3 \epsilon.
\]
Note that $g(\alpha_k) + f(\alpha_k) = 1$. As a result, we have
\[
\sum_{k=1}^{K} \frac{f(\alpha_k)}{\lambda_k} - c_3 \epsilon \leq \frac{\|V - W^* H^T\|_F^2}{\|V\|_F^2} \leq \sum_{k=1}^{K} \frac{f(\alpha_k)}{\lambda_k} + c_2 \epsilon.
\]
Thus, with probability at least $1 - 6K \exp(-t^2 F)$, we have
\[
\frac{\|V - W^* H^T\|_F}{\|V\|_F} \leq \sqrt{\sum_{k=1}^{K} \frac{1}{\lambda_k}} \frac{f(\alpha_k)}{\lambda_k} \leq c_4 \epsilon,
\]
where $c_4$ depends on $K$ and $\{(\alpha_k, \lambda_k) : k \in [K]\}$. 

**APPENDIX B**

**PROOF OF THEOREM 9**

We first state and prove the following lemma.

**Lemma 14:** Suppose data matrix $V$ is generated as in Theorem 6 with all the circular cones being contained in $P$, then the expectation of the covariance matrix $v_1 v_1^T$ is
\[
\mathbb{E} [v_1 v_1^T] = \frac{K}{K(F-1)} \sum_{k=1}^{K} \frac{f(\alpha_k) / \lambda_k}{\lambda_k} \mathbb{E} [u_k u_k^T],
\]
where $v_1$ denotes the first column of $V$.

**Proof:** From the proof in Lemma 11, we know if we always take $e_1$ to be the original vector for the Householder transformation, the corresponding Householder matrix for the $k$-th circular cone $C_k$ is given by (47) and we have
\[
\mathbb{E} [v_1 v_1^T] = \frac{K}{K} \sum_{k=1}^{K} \frac{P_k D_k P_k^T}{\lambda_k},
\]
where $D_k$ is a diagonal matrix with the first diagonal entry being $f(\alpha_k) := \frac{1}{2} + \frac{\sin(2\alpha_k)}{4\alpha_k}$ and other diagonal entries are
\[
\frac{f(\alpha_k)}{\lambda_k} = \frac{1}{F-1} - \frac{\sin(2\alpha_k)}{4\alpha_k}.
\]
We simplify $P_k D_k P_k^T$ using the property that all the $F - 1$ diagonal entries of $D_k$ are the same. Namely, we can write
\[
P_k = I - 2u_k u_k^T = I - \frac{(e_1 - u_k)(e_1 - u_k)^T}{1 - u_k(1)}
\]
\[
= \begin{bmatrix}
    u_k(1) & u_k(2) & \cdots & u_k(F) \\
    u_k(2) & 1 - u_k(1)^2 & \cdots & -u_k(2) u_k(F) \\
    \vdots & \vdots & \ddots & \vdots \\
    u_k(F) & -u_k(F) u_k(2) & \cdots & 1 - u_k(F)^2
\end{bmatrix}.
\]
Note that $P_k = [p_1^k, p_2^k, \ldots, p_F^k]$ is symmetric and the first column of $P_k$ is $u_k$. Let $D_k$ be the diagonal matrix with diagonal entries being $d_1, d_2, \ldots, d_F$. Then we have
\[
P_k D_k P_k^T = \sum_{j=1}^{K} d_j p_j^k (p_j^k)^T
\]
\[
= d_1 u_k u_k^T + d_2 \sum_{j=2}^{K} p_j^k (p_j^k)^T
\]
\[
= g(\alpha_k) u_k u_k^T + \frac{f(\alpha_k)}{F-1} (I - u_k u_k^T)
\]
\[
= \frac{f(\alpha_k)}{F-1} I + \left( g(\alpha_k) - \frac{f(\alpha_k)}{F-1} \right) u_k u_k^T.
\]
Thus, we obtain (78) as desired. We are now ready to prove Theorem 9.

**Proof of Theorem 9:** Define

\[ a := \frac{\sum_{k=1}^{K} f(\alpha) / \lambda}{K(F - 1)} = \frac{f(\alpha) / \lambda}{F - 1}, \tag{87} \]

\[ b := \frac{g(\alpha) - f(\alpha) / (F - 1)}{K\lambda}. \tag{88} \]

By exploiting the assumption that all the \(\alpha_k\)'s and \(\lambda_k\)'s are the same, we find that

\[ E[v_i v_i^T] = aI + b \sum_{k=1}^{K} u_k u_k^T. \tag{89} \]

Let \(U = [u_1, u_2, \ldots, u_K]\). We only need to consider the eigenvalues of \(\sum_{k=1}^{K} u_k u_k^T = UU^T\). The matrix \(UU^T\) has some non-zero eigenvalues as that of \(UU^T\). Furthermore,

\[ UU^T = \begin{bmatrix} 1 & \cos \beta & \cdots & \cos \beta \\ \cos \beta & 1 & \cdots & \cos \beta \\ \vdots & \vdots & \ddots & \vdots \\ \cos \beta & \cos \beta & \cdots & 1 \end{bmatrix} = (\cos \beta) ee^T + (1 - \cos \beta)I \tag{90} \]

where \(e \in \mathbb{R}^K\) is the vector with all entries being 1. Therefore, the eigenvalues of \(UU^T\) are \(1 + (K - 1)\cos \beta, 1 - \cos \beta, \ldots, 1 - \cos \beta\). Thus, the vector of eigenvalues of \(E[v_i v_i^T]\) is \([a + b(1 + (K - 1)\cos \beta), a + b(1 - \cos \beta), \ldots, a + b(1 - \cos \beta), a, a, \ldots, a]\).

By Lemmas 2 and 13, we deduce that for any \(t \geq 1\) and a sufficiently small \(\epsilon > 0\), such that

\[ a + \epsilon < a + b(1 - \cos \beta) - \epsilon, \tag{92} \]

then if \(N \geq c(t/\epsilon)^2 F\) (where \(c > 0\) depends only on \(\lambda, \alpha, \beta\)), then with probability at least \(1 - 2(K_{\max} - K_{\min} + 1) \exp(-t^2 F)\), Eqn. (46) holds.

**Acknowledgements**

The authors would like to thank the three anonymous reviewers for their excellent and detailed comments that helped to improve the presentation of the results in the paper.

Zhaoqiang Liu was born in China in 1991. He is currently a Ph.D. candidate in the Department of Mathematics at National University of Singapore (NUS). He received the B.Sc. degree in Mathematics from the Department of Mathematical Sciences at Tsinghua University (THU) in 2013. His research interests are in machine learning, including unsupervised learning such as matrix factorization and deep learning.

Vincent Y. F. Tan (S’07-M’11-SM’15) was born in Singapore in 1981. He is currently an Assistant Professor in the Department of Electrical and Computer Engineering (ECE) and the Department of Mathematics at the National University of Singapore (NUS). He received the B.A. and M.Eng. degrees in Electrical and Information Sciences from Cambridge University in 2005 and the Ph.D. degree in Electrical Engineering and Computer Science (EECS) from the Massachusetts Institute of Technology in 2011. He was a postdoctoral researcher in the Department of ECE at the University of Wisconsin-Madison and a research scientist at the Institute for Infocomm (I²R) Research, A*STAR, Singapore. His research interests include network information theory, machine learning, and statistical signal processing.

Dr. Tan received the MIT EECS Jin-Au Kong outstanding doctoral thesis prize in 2011 and the NUS Young Investigator Award in 2014. He has authored a research monograph on “Asymptotic Estimates in Information Theory with Non-Vanishing Error Probabilities” in the Foundations and Trends in Communications and Information Theory Series (NOW Publishers). He is currently an Editor of the IEEE Transactions on Communications and the IEEE Transactions on Green Communications and Networking.
