ABSTRACT

Launched on 2008 June 11, the Large Area Telescope (LAT) instrument on board the Fermi Gamma-ray Space Telescope has provided a rare opportunity to study high-energy photon emission from gamma-ray bursts (GRBs). Although the majority of such events (27) have been identified by the Fermi-LAT Collaboration, four were uncovered by using more sensitive statistical techniques. In this paper, we continue our earlier work by finding three more GRBs associated with high-energy photon emission, GRB 110709A, 111117A, and 120107A. To systematize our matched filter approach, a pipeline has been developed to identify these objects in nearly real time. GRB 120107A is the first product of this analysis procedure. Despite the reduced threshold for identification, the number of GRB events has not increased significantly. This relative dearth of events with low photon number prompted a study of the apparent photon number distribution. We find an extremely good fit to a simple power law with an exponent of $-1.8 \pm 0.3$ for the differential distribution. As might be expected, there is a substantial correlation between the number of lower energy photons detected by the Gamma-ray Burst Monitor (GBM) and the number observed by LAT. Thus, high-energy photon emission is associated with some but not all of the brighter GBM events. Deeper studies of the properties of the small population of high-energy emitting bursts may eventually yield a better understanding of these entire phenomena.

Key word: gamma-ray burst: individual (GRB 110709A, GRB 111117A, GRB 120107A)

1. INTRODUCTION

Most gamma-ray burst (GRB) detections have been limited to photons below a few MeV. High-energy emission above 100 MeV was only detected a few times by the EGRET instrument (Dingus 1995) and more recently by AGILE (Giuliani et al. 2008). The Fermi Gamma-ray Space Telescope, launched in 2008, has enlarged the opportunity to study high-energy emission from GRBs by providing a large aperture and wide field of view (FOV). There are two instruments on board the Fermi satellite: the Gamma-ray Burst Monitor (GBM; Meegan et al. 2009) and the Large Area Telescope (LAT; Atwood et al. 2009). These detectors overlap energy bands to span from 8 keV to above 100 GeV. At the current moment, there are several GBM instruments in orbit that can provide significantly more precise localizations (e.g., Swift; Gehrels et al. 2004, INTEGRAL; Winkler et al. 2003, and AGILE; Giuliani et al. 2008). This combination provides a unique opportunity to study the physical mechanisms of GRBs across the entire electromagnetic spectrum.

Fermi-LAT covers a photon energy range from below 20 MeV to more than 300 GeV with an effective FOV $\sim$ 2.4 sr (Atwood et al. 2009) while the second Fermi instrument, the GBM, is sensitive to the range from 8 keV to 40 MeV. The GBM covers the entire sky except that occulted by the Earth. Real-time GRB triggers are generated by the GBM (Meegan et al. 2009) at a rate of $\sim$ 250 events per year (Paciesas et al. 2010). However, of those events simultaneously observed by LAT, only 27 have been detected at a threshold of more than $\sim$ 10 high-energy photons\(^8\), corresponding to a rate of $\sim$ 9 GRBs per year (Granot 2010).

Using the matched filter technique, the Fermi detection threshold was reduced to a level of $\sim$ 6 high-energy photons with the concomitant identification of four additional detections as reported by Akerlof et al. (2010, 2011, hereafter A10, A11) and Zheng et al. (2012, hereafter Z12), namely, GRB 080905A, 091208B, 090228A, and 081006A. In Section 2, we present the high-energy photon detection of three new GRBs using this matched filter technique. We discuss the photon count distribution of these events and their correlations at lower energies in Section 4 and summarize our conclusions in Section 5.

2. DETECTION OF GRB 110709A, 111117A AND 120107A USING THE MATCHED FILTER TECHNIQUE

Following the method developed by Akerlof et al. in A10 and A11, we have searched the GRB database generated by the GBM and Swift from the end of the period covered by our earlier papers, A10, A11, and Z12, up to 2012 January 15. For the GBM, the catalog\(^9\) extraction start date is 2010 July 10 following the period studied by A10 and Z12, while for Swift, the comparable catalog\(^10\) extraction started at 2010

\(^9\) http://heasarc.gsfc.nasa.gov/W3Browse/fermi/fermigtrig.html
\(^10\) http://swift.gsfc.nasa.gov/docs/swift/archive/grb_table.html/
April 1, following the period reported in A11. These two periods correspond to 554 and 654 days during which the respective instruments recorded 348 and 149 GRB events. For the following analysis, the data can be divided into two sets: events triggered by the GBM alone and events triggered by Swift with or without the GBM. Since the angular resolution of Swift is considerably better, any additional information from the GBM provides no further constraints. Events of interest must be visible to LAT, which imposes a boresight angle restriction of less than 74°. One hundred ninety-one GBM and forty-three Swift triggers pass this LAT acceptance criterion including fifteen GBM/Swift simultaneous detections. For the GBM-tagged events which impose looser restrictions on the burst location, we attempted to set a fluence lower limit of 5 \( \mu \text{erg cm}^{-2} \). Consistent with recommendations from the Fermi Science Support Center, the LAT photon directions with respect to the zenith were required to be less than 105°. The selection of high-energy GRB candidates presented in this paper is based on the criterion that the number of random background events with greater or equal matched filter weight within the appropriate trigger classification be less than 0.05 events (i.e., 5% false positive probability).

The matched filter weight prescriptions for the GBM and Swift-triggered data are given in papers A10 and A11, respectively. The principle difference is that the poorer angular resolution of the GBM demands an additional clustering function. The cumulative distributions for random events drawn in green in Figures 2 and 3 of the two respective papers are shown in Figure 1 along with arrows that indicate the values of the matched filter weights for the three GRB events described below. The actual time duration of an event does not directly modify the matched filter weight algorithm—the analysis uses a standard time window of 47.5 s in all cases.
Figure 3. LAT photon light curves for GRB 110709A (first panel for 0–50 s and second panel for 0–250 s), 111117A (third panel), and 120107A (fourth panel). The filled circles represent the energy for each photon.

(A color version of this figure is available in the online journal.)

Note that there were two changes to the LAT data format during the search period covered by this paper. First of all, class 4 (ultraclean photon) has been officially assigned to photons since 2011 April. Since this is a proper subset of class 3 (clean), we treat class 4 photons the same as class 3 in this analysis. Second, the LAT data stream processing was switched from Pass 6 to Pass 7 after 2011 August 6. Since Pass 6 data are no longer available, we are restricted to Pass 7 data following this date.

2.1. GRB 120107A Detected from the GBM Catalog

GRB 120107A is a long burst trigger detected by the GBM (trigger 347620337; McBreen 2012) at 09:12:15 UT with $T_{90} = 23$ s. The initial GBM trigger\textsuperscript{11} gives R.A. = 223\textdegree10, decl. = −77\textdegree96 with an uncertainty of 7\textdegree. Our pipeline localized the GRB from the LAT data (Zheng & Akerlof\textsuperscript{2012a}) to R.A. = 246\textdegree40, decl. = −69\textdegree93 with an uncertainty of 0\textdegree.5, 10\textdegree from the GBM estimate. Eight high-energy photons in LAT data above 100 MeV were found to be associated with the GRB with the highest energy of 1.78 GeV at 8.1 s after the trigger and a total of two photons with energy greater than 1 GeV. The matched filter weight value is $\zeta \sum w_i = 212.704$. The random background probability for such a value is $2.9 \times 10^{-4}$ corresponding to an estimated background of 0.019 events over the set of GBM triggers.

One concern for this detection is an observing direction from the LAT that was close to Earth’s limb with zenith angle $\sim 100^\circ$. At such locations, there is possible photon contamination arising from charged particle interactions with Earth’s atmosphere. As recommended by the Fermi Science Support Center,
a photon zenith angle cut of less than 105° was maintained. To address any remaining doubts, an additional check was performed to test if atmospheric interactions could mimic a GRB signal. Nine hundred fifty-seven random fields were obtained at similar boresight and zenith angles. None of these 957 random fields have a matched weight value exceeding GRB 120107A ($\sum wi = 212.704$) and the maximum matched weight for the ensemble was $\sum wi = 20.3$. Thus, the false positive probability for detection of GRB 120107A is less than 0.1%.

2.2. GRB 110709A Detected from the Swift Catalog

GRB 110709A is a long burst detected by both Swift (Holland et al. 2011) and GBM (Connaughton 2011) with $T_90 = 50$ s. No optical afterglow was found (e.g., Xin et al. 2011). Ten high-energy LAT photons above 100 MeV are found to be associated with the GRB within our time window. The highest energy photon for GRB 110709A is 3.1 GeV at 42.1 s after the trigger. Our analysis estimates a matched weight value $\sum wi = 18.3$. Using the prescription described earlier, the estimated random event background is 0.0098 over the entire 43 Swift trigger set.

Like many other LAT GRBs, considerable high-energy emission extends to 250 s (e.g., GRB 080825C, Abdo et al. 2009d; GRB 080916C, Abdo et al. 2009c; GRB 090510, Abdo et al. 2009b; GRB 090902B Abdo et al. 2009a). A single photon greater than 1 GeV was also detected at 234.2 s post-trigger. However, due to spacecraft slewing, the LAT boresight angle for the GRB location moved quickly from 53° when the burst occurred to greater than 80° within 100 s. At such large boresight angles, the LAT instrument sensitivity is greatly reduced and inferences about extended emission after 100 s needs to be taken with caution. We have listed the extended emission photons after 47.5 s separately from the photon within 47.5 s in Table 1.

2.3. GRB 111117A Detected from the Swift Catalog

Interestingly, GRB 111117A is a short GRB detected by both Swift (Mangano et al. 2011; Sakamoto et al. 2012) and GBM (Foley & Jenke 2011) with $T_90 = 0.6$ s but no reported optical afterglow. It is the only short GRB presented in this paper but with 47.5 s durations obtained from exactly the same celestial fields have a matched weight value exceeding GRB 110707A. Since GRB 111117A is well localized by Swift, the same weight calculations were performed on 1188 LAT data sets and inferences about extended emission after 100 s needs to be taken with caution. We have listed the extended emission photons after 47.5 s separately from the photon within 47.5 s in Table 1.

Table 1

2.4. Pipeline for Near Real-time Detection

In the process of performing this work, a pipeline for automatically downloading and analyzing LAT data has been developed based on IDL software using the matched filter technique. The results are distributed online. This opens the possibility to detect LAT GRBs in near real time once the LAT data are available. In fact, GRB 120107A was the first LAT GRB identified by the pipeline and was announced immediately (Zheng & Akerlof 2012a). A Swift/XRT ToO observation was requested and approved but unfortunately could not be performed since the GRB location was close to the Sun. As this manuscript was being completed, another GRB 120316A (Zheng & Akerlof 2012b) was detected by our LAT data pipeline and confirmed in location by the IPN Collaboration (Hurley et al. 2012). The successful detection of GRB 120107A and 120316A by our technique provides an opportunity for guiding optical follow-up observations using the higher accuracy of the matched filter LAT localizations. Prior to the Fermi launch, we expected that the LAT would provide prompt estimates of GRB locations with error circles of the order of a few degrees in radius that would enable ground-based facilities with large fields of view such as our ROTSE project to locate the optical counterparts quickly enough to enable a wide variety of observations at all wavelengths. We soon learned that the LAT data stream was constrained to infrequent downlinks so such possibilities were eliminated by the mission design. Given the low rate of GRB detections, we came to the conclusion that any increase in the number of identified events would be useful. By applying the matched filter techniques to the LAT data, we have identified seven GRBs so far in LAT data, clearly demonstrating the possibility to detect LAT GRBs in near real time once the LAT photon counts used in the following analysis are determined by the number of quanta with weights greater than 0.1, corrected for the instrument effective area, a function of the bandpass angle corrected photons, with units of: photons m⁻² (47.5 s)⁻¹. For the LAT GRB subsample based on the matched filter technique, the time window is restricted to the 47.5 s interval following the associated GBM trigger. Twenty-two GRBs match these criteria including the seven new identified events described here and in our earlier papers. The LAT photon counts used in the following analysis are determined by the number of quanta with weights greater than 0.1, corrected for the instrument effective area, a function of the LAT boresight angle obtained from the Fermi Science Support Center. Table 2 lists the GRBs included in this analysis.

First of all, the total number of events in this sample is quite small and covers a large dynamic range (roughly a factor of 100). Thus, any satisfactory fitting technique must avoid sensitivity to arbitrary data binning. We have turned to the Smirnov–Cramér–Von Mises (S-C-VM) statistic (Eadie et al. 1971) to achieve such independence. The input to the fitting process started with the random selection of an event direction with respect to the LAT z-axis restricted by the maximum boresight acceptance angle of 74°. The photon number was generated by the inversion of the formula for the cumulative distribution of a power law and multiplied by the LAT effective area. For each event, the number of photons was tested against estimates of the matched filter detection efficiency computed earlier in the course of this investigation. The results are shown in Figure 4. The best fit was obtained with an exponent of −1.8 ± 0.3 for the differential distribution. For this value, the S-C-VM statistic estimated that 84% of all samples selected from the same parent distribution would be more poorly matched. This result with a cumulative distribution exponent of −0.8 is significantly different than the −3/2 value for bright GBM events for which the S-C-VM test would predict about

\[ \text{Observed photons with matched weight greater than 0.1, with units of: photons (47.5 s)}^{-1}. \]

\[ \text{Boresight angle corrected photons, with units of: photons m}^{-2} \text{ (47.5 s)}^{-1}. \]

---

**Table 2**

| Name          | Boresight Angle(°) | Photons² | Photons² |

the interval between the first and last event in Table 2, 838 homogeneous distribution. During the 1230 days that span be detected with energetic photons if they originate from a components.

argument for dividing the sample into separate dim and bright by a simple power law also suggests that there is no compelling likelihood. The high probability that the actual data are fit by a simple power law also suggests that there is no compelling argument for dividing the sample into separate dim and bright components.

The natural next question is how many GRBs might possibly be detected with energetic photons if they originate from a homogeneous distribution. During the 1230 days that span the interval between the first and last event in Table 2, 838 GBM GRB triggers were recorded. Using the spacecraft flight information and the power-law distribution of LAT photon count determined above, we find that 32.8% or 275 events would have been detected at high energies, a factor of 12 times greater than that has been obtained. Why some GRBs emit high-energy photons but most do not is one of the most critical questions facing this subfield of astrophysics.

One obvious possibility is that LAT GRBs are specifically associated with only the events that are brightest at lower energies. Thus, we need to explore possible correlations with low-energy data obtained simultaneously from the GBM. For reasons mentioned above, we have chosen to use an estimator of the total photon number in the GBM energy range determined by the product of $T_{50}$ and the peak flux over a 1024 ms interval. This permits the comparison of the number of LAT photons with the number of GBM photons. For the 22 events listed in Table 2, 5 were omitted because their $T_{50}$ duration was less than 1 s. The remaining 17 are plotted in Figure 5. Although there is wide dispersion, a Pearson correlation coefficient of 0.537 indicates that the fluxes are correlated with a probability of 99.4%. We have adopted the event median photon count as a robust estimator of GBM intensity. For the 18 events in Figure 5, this corresponds to a count of 205 photons in the GBM energy band. Relative to the entire GBM catalog, this is only the brightest 12.3%. Doubling this number, we estimate that out of the 275 GBM events that were observable within the LAT FOV, only 68 would have been associated with a high enough GBM flux. This is still a factor of three greater than observed. Two conclusions emerge: (1) LAT GRB events are strongly associated with luminous GBM events and (2) even after accounting for the luminosity bias, a substantial fraction of GRBs still do not emit detectable high-energy photons. The fact that, occasionally, short-duration GRBs are also found to be high-energy photon emitters suggests that this phenomenon is a generic property of energetic jets uncorrelated with the details of the progenitor. We still cannot offer any idea why the apparent photon count distribution is described by such a slowly decreasing power law.

4. SUMMARY

We have described three new LAT GRBs identified by the matched filter technique. GRB 120107A was selected with the aid of the GBM catalog while GRB 110709A and 111117A were tagged by Swift. We have explored the distributions of photon counts from both GBM and LAT energy ranges. The shallow power-law distribution of the numbers of photons in each event and the apparent correlation with lower energies is an intriguing development which should be tested with greater statistics. We hope that this has begun to address the mysterious nature of the relation between the very large number of GBM events and the much smaller subset at higher energies. Given the low statistics of the latter, we hope every effort will be made to encourage the most efficient search techniques of the available data stream (see also Rubtsov et al. 2012).

We thank the anonymous referee for helpful comments and suggestions for improving this manuscript. We gratefully acknowledge the assistance of Valerie Connaughton at the Marshall Space Flight Center and Chris Shrader at the Fermi Science Support Center for their help in obtaining specific GBM data and providing information about some detailed aspects of the Fermi mission. This research is supported by the NASA Grant NNX08AV63G and the NSF Grant PHY-0801007.
