(Dated: September 24, 2020)

Entanglement measures are useful tools in characterizing otherwise unknown quantum phases and indicating transitions between them. Here we examine the concurrence and entanglement entropy in quantum spin chains with random long-range couplings, spatially decaying with a power-law exponent α. Using the strong disorder renormalization group (SDRG) technique, we find by analytical solution of the master equation a strong disorder fixed point, characterized by a fixed point distribution of the couplings with a finite dynamical exponent, which describes the system consistently in the regime α > 1/2. A numerical implementation of the SDRG method yields a power law spatial decay of the average concurrence, which is also confirmed by exact numerical diagonalization. However, we find that the lowest-order SDRG approach is not sufficient to obtain the typical value of the concurrence. We therefore implement a correction scheme which allows us to obtain the leading order corrections to the random singlet state. This approach yields a power-law spatial decay of the typical value of the concurrence, which we derive both by a numerical implementation of the corrections and by analytics. Next, using numerical SDRG, the entanglement entropy (EE) is found to be logarithmically enhanced for all α, corresponding to a critical behavior with an effective central charge c = ln2, independent of α. This is confirmed by an analytical derivation. Using numerical exact diagonalization (ED), we confirm the logarithmic enhancement of the EE and a weak dependence on α. For a wide range of distances l, the EE fits a critical behavior with a central charge close to c = 1, which is the same as for the clean Haldane-Shastry model with a power-law-decaying interaction with α = 2. Consistent with this observation, we find using ED that the concurrence shows power law decay, albeit with smaller power exponents than obtained by SDRG. We also present results obtained with DMRG and find agreement with ED for sufficiently small α < 2, whereas for larger α DMRG tends to underestimate the entanglement entropy and finds a faster decaying concurrence.

I. INTRODUCTION

Long-range interactions in disordered quantum many-body systems arise in a variety of physical contexts. For example, randomly placed magnetic impurities in doped semiconductors are known to interact with each other via exchange couplings that depend on their separation distance. While in insulating regimes these interactions typically decay exponentially, $J(r) \propto \exp(-r/\xi)$, in the metallic regime they are mediated via the RKKY mechanism, and therefore decay with a power law, $J(r) \propto r^{-d}$, where d is the dimension of the host system. Power-law random long-range interactions have also been found to occur in quantum glasses, where tunneling ions form local two-level systems which are interacting by dipole-dipole and elastic interactions. More recently, tunable long-range Heisenberg interactions have been demonstrated in quantum simulators based on trapped ions.

There have been many theoretical studies of quantum spin chains with random short-range interactions. For example, it is known that bond disorder drives spin-1/2 Heisenberg chains with short-ranged antiferromagnetic interactions into an infinite-randomness fixed point (IRFP), characterized by a critical ground state, i.e. a product state of singlets which are formed at random distances. The entanglement entropy of such critical spin chains scales logarithmically, with a central charge $c = \ln 2$ of the corresponding conformal field theory. As the IRFP is a critical point, the entanglement entropy is logarithmically enhanced. The corresponding central charge $c$ is, however, smaller by a factor ln2 than the central charge of the corresponding clean spin chain. This has been derived using the strong disorder renormalization group (SDRG) method.
More recently, the SDRG has also been applied to disordered quantum spin systems with long-range interactions, where it has been shown to lead to a self-consistent description of its thermodynamic properties in terms of a novel strong disorder fixed point$^{11,12}$. However, quantum information theoretical measures, such as the entanglement entropy and the concurrence have not yet been studied in such systems. Here, we analyze these quantities for disordered quantum spin-1/2-chains with long-range power-law couplings, decaying with a power-law exponent $\alpha$, using the SDRG, exact diagonalization (ED), and density matrix renormalization group (DMRG). There have been indications that such systems undergo a phase transition at a critical decay exponent $\alpha_\text{c}$ from a localized regime for $\alpha > \alpha_\text{c}$, to a delocalized regime for $\alpha < \alpha_\text{c}$,$^{11}$ similar to the delocalization transition of disordered fermions with long-range hoppings$^{13,14}$. Thus, a logarithmic enhancement of the average entanglement entropy is expected at some value of $\alpha$. Moreover, since the spin-1/2 Haldane-Shastry model, a Heisenberg model with power-law long-range interactions, is known to be critical for $\alpha = 2$ with a conformal charge $c = 1$,$^{15,16}$ and as it was suggested in Ref. 9 that disordered spin chains are critical when the clean spin chain is critical with a central charge $\hat{c}$, smaller by a factor $\ln 2$ than the central charge of the clean critical spin chain, one could expect a logarithmic enhancement of the entanglement entropy at $\alpha = 2$ with $\hat{c} = \ln 2$ in the presence of disorder. This motivates us to examine the entanglement properties of disordered quantum spin systems with long-range power-law couplings as a function of the power exponent $\alpha$.

Here, we focus on the bond disordered XX-spin chain with long-range couplings, defined by the Hamiltonian

$$H = \sum_{i<j} J_{ij} \left( S_i^x S_j^x + S_i^y S_j^y \right),$$

(1)

describing $N$ interacting $S = 1/2$ spins that are randomly placed at positions $\mathbf{r}_i$ on a lattice of length $L$ and lattice spacing $a$, with density $n_0 = N/L = 1/l_0$, where $l_0$ is the average distance between them. The couplings between all pairs of sites $i, j$, are taken to be antiferromagnetic and long-ranged, decaying with a power law,

$$J_{ij} = J_0 |(\mathbf{r}_i - \mathbf{r}_j)/a|^{-\alpha}.$$  

(2)

The random placement of the spins on the lattice sites, excluding double occupation, results in an initial (bare) distribution of the separation distance $l$ between pairs of spins, $p^0(l)$, yielding an initial distribution of couplings $J$, $P^0(J)$. For example, for $N = 2$ it is given exactly by $p^0(l) = (1-l/L)^2/(L-1)$, where we set $a = 1$, which yields an initial distribution of couplings $J$,

$$P^0(J) = \frac{2}{(L-2)\alpha J_0} \left( \frac{J_0}{J} \right)^{1+1/\alpha} - \frac{1}{L} \left( \frac{J_0}{J} \right)^{1+2/\alpha},$$

(3)

for couplings restricted to the interval $J_0((L-1)/a)^{-\alpha} < J < J_0$. It is important to note that in the case of long-range interactions, this model does not simply map onto an effective fermionic tight-binding model with long-range hoppings, because the phase factors arising in the Jordan-Wigner transformation are non-trivial.

**II. THE STRONG DISORDER RENORMALIZATION GROUP**

Here we describe how to apply the SDRG to this model, with the aim to evaluate the concurrence and the entanglement entropy$^{17}$. Choosing the pair with the largest coupling $(i, j)$, which forms a singlet (see Fig. 1), we take the expectation value of the Hamiltonian in that particular singlet state within second-order perturbation in couplings with all other spins$^{18}$. This yields the long-range renormalization rule for the couplings between spins $(l, m)$ in the XX model,$^{11,12}$

$$(J_{lm}^x)' = J_{lm}^x - \frac{(J_{li}^x - J_{lj}^x)(J_{jm}^x - J_{jm}^x)}{J_{ij}^x}. \quad (4)$$

For the Heisenberg model, this rule differs by a numerical prefactor $1/2^{11,12}$. Previously it was found that in long-range coupled disordered quantum spin chains there is a strong disorder fixed point$^{12}$. This was realized by inspecting the evolution of the width of the distribution of couplings $J$ with the RG flow. In the short-range case, i.e., at the infinite randomness fixed point (IRFP), this distribution gets wider at every RG step, with width $W = (\ln(J/\Omega_0)^2) - (\ln(J/\Omega_0)^2))^{1/2} = \ln(\Omega_0/\Omega) = \Gamma_{\Omega}$, increasing monotonically as the RG scale $\Omega$ is lowered. In contrast, for long-range couplings with finite $\alpha$ the width $W$ saturates and converges to $W = \Gamma$, with $\Gamma = 2\alpha$ in the XX-limit$^{12}$. The convergence to a finite dynamical exponent $\Gamma$ characterizes the new strong disorder fixed point (SDFP). For large number of spins $N$, and in the limit of a small RG scale $\Omega$, the resulting distribution function of renormalized couplings $J$ at RG scale $\Omega$ was found to converge to$^{7}$,

$$P(J, \Omega) = \frac{1}{\Omega_{\Omega}} \left( \frac{\Omega}{J} \right)^{1-1/\Gamma_{\Omega}}.$$  

(5)

At the IRFP, $\Gamma_{\Omega}$ increases monotonically as $\Gamma_{\Omega} = \ln(\Omega_0/\Omega)$, when $\Omega$, the largest energy at this renormalization step, is lowered. Here $\Omega_0$ is the initially largest energy in the SC.

![FIG. 1. Decimation of the strongest-coupled pair $i,j$ (thick line) generates effective couplings between other spins $l,m$ (dotted line).](image-url)
At the SDFP, however, $\Gamma^{\alpha}$ is found to converge to an asymptotic finite value $\Gamma^{\alpha} \rightarrow 2\alpha^{12}$, yielding a narrower distribution with finite width $\Gamma$. We note that this distribution is less divergent as $J \rightarrow 0$ than the initial distribution $E_{Q}^{(3)}$. In order to check whether Eq. (5) is indeed a fixed point distribution of the RG with RG rule Eq. (4), we first present an analytical derivation. The master equation governing the renormalization process is a differential equation for the distribution function $P(J, \Omega)$, given by

$$
- \frac{\partial P(J, \Omega)}{\partial \Omega} = P(\Omega, \Omega) \left( \prod_{i=1}^{5} dJ_{i} P(J_{i}, \Omega) \right) \times \delta \left( J - J_{5} + \frac{(J_{1} - J_{2})(J_{3} - J_{4})}{\Omega} \right).
$$

The numbering of the couplings is defined in Fig. 2. In order to proceed, let us note that the renormalization correction to the bare coupling $J_{5}$, given by $\delta J = (J_{1} - J_{2})(J_{3} - J_{4})/\Omega$, is always smaller than $J_{5}$, $\delta J < J_{5}$, as can be checked numerically. Performing first the integral over $J_{5}$, we can expand the distribution function of $J_{5} = J + \delta J$ in $\delta J$, finding to all orders in $\delta J$

$$
- \frac{\partial P(J, \Omega)}{\partial \Omega} = P(\Omega, \Omega) \sum_{n=0}^{\infty} \frac{1}{n!} \left( \left( \frac{(J_{1} - J_{2})(J_{3} - J_{4})}{\Omega} \right)^{n} \right) \frac{\partial^{n} P(J, \Omega)}{\partial^{n} J},
$$

where $\langle \ldots \rangle$ denotes the averaging with the distribution functions $P(J_{i}, \Omega)$, for $i = 1, 2, 3, 4$. Thus, we find

$$
- \frac{\partial P(J, \Omega)}{\partial \Omega} = P(\Omega, \Omega) \left( 1 + \sum_{n=2}^{\infty} \frac{A_{n}}{n!} \Omega^{n} \frac{\partial^{n} P(J, \Omega)}{\partial J} \right) P(J, \Omega),
$$

where

$$
A_{n} = \left( \frac{(J_{1} - J_{2})(J_{3} - J_{4})}{\Omega^{2}} \right)^{n}. \tag{8}
$$

We see that the strong disorder scaling ansatz Eq. (5) is a solution of Eq. (7) for $\Omega \rightarrow 0$ with $\mu = 1/\Gamma = \text{const.}$, when neglecting all renormalization corrections given by the terms $n \geq 2$. To solve Eq. (7), including the correction terms, we make the ansatz

$$
P(J, \Omega) = \frac{1}{\Omega} p(x = J/\Omega), \tag{9}
$$

where the probability density function $p(x)$ is to be derived with the condition that $p(1) = \mu$, so that $p(x) = p^{\alpha}(x) = \mu x^{\alpha-1}$ corresponds to strong disorder scaling Eq. (5) with $\mu = \text{const.}$. Inserting this ansatz, we find the following ordinary differential equation for $p(x)$,

$$
(1 - \mu)p(x) + \frac{\partial}{\partial x} p(x) = \sum_{n=2}^{\infty} \frac{A_{n}}{n!} \frac{\partial^{n} p(x)}{\partial x}, \tag{10}
$$

with the condition $p(1) = \mu$. 

\[FIG. 2.\] Definition of couplings between removed spins $i, j$ and other spins $l, m$ (dotted lines).

\[FIG. 3.\] Probability density function $p^{\alpha}(x = J/\Omega)$ on a double logarithmic scale for $\mu = 0.1$ (blue) to $\mu = 0.9$ (magenta) in steps of 0.1. Inset: Magnification showing the exponential decay to $\mu$ as $x = J/\Omega \rightarrow 1$.

\[FIG. 4.\] Probability density function $p(x = J/\Omega)$ on a double logarithmic scale for $\mu = 0.1$ (blue) to $\mu = 0.9$ (magenta) in steps of 0.1. Inset: Magnification showing the exponential decay to $\mu$ as $x = J/\Omega \rightarrow 1$. 

Choosing an iterative approach, we can first approximate the coefficients $A_n$, by setting $p(x) = p^0(x) = \mu x^{\mu-1}$ in Eq. (9), yielding

$$A_n \approx \frac{\mu^4 x^2 (\mu) \Gamma^2(n+1)}{(\frac{\mu}{2} + \mu)^2 \Gamma^2(\mu + n + 1)}. \quad (11)$$

We note that $A_n \sim 1/n^2$ for $0 < \mu \ll 1$. For $n = 2$, this simplifies with $\Gamma(z+1) = \Gamma(z)$ to $A_2 = 4\mu^2/((\mu+2)^2(\mu+1)^4)$, and we can solve to second order $n = 2$ the resulting 2nd order ordinary differential equation exactly in terms of products of Hermite polynomials and Hypergeometric functions, as plotted in Fig. 4. For comparison, we plot $p^0(x) = \mu x^{\mu-1}$ in Fig. 3. We see that $p(x)$ has the same power law $p(x) \sim x^{\mu-1}$ dependence for intermediate $0 \ll x = J/\Omega < 1$ as $p^0(x)$, but converges for $x \to 0$ to a constant which depends on $\mu$ approximately as $p(x \to 0) \approx 1/\mu^{3/4}$. We note that for small $0 < \mu \ll 1$, $A_n \sim 4\mu^2/n^2$, so that higher order terms decay fast with $n$, and the pdf $p(x)$ obtained for $n = 2$ is a good approximation for small $\mu < 1$.

An alternative way to solve the master equation, is to make use of a step which is commonly used to calculate the generating function of a distribution: we multiply the pdf $\{\Gamma(\Omega) = 1\}$ by $z$, where $z$ is a real number, and then integrate both sides over $J$. Thereby, one can generate all moments of the distribution by partial derivatives in $z$ and thus the entire distribution function. Since we are interested in the fixed point solution for large systems, we set the lower integration limit to 0. The upper integration limit is provided by $\Omega$. We next insert the ansatz for the distribution of renormalized couplings Eq. (5), and find a differential equation for the exponent $\mu(\Omega) = 1/\Gamma(\Omega)$ (a detailed derivation is provided in Appendix A),

$$\sum_{n=1}^{\infty} \frac{-\mu'(\Omega)(\Omega t)^n}{(n-1)!(\mu + n)^2} = \sum_{k=1, k'=0}^{\infty} \frac{\mu^k(\Omega)}{(k + \mu)^2 \Gamma^2(\mu + 2k + 1)k!}(\mu + k')\Omega, \quad (12)$$

Here, $\Gamma(x)$ is the standard Gamma function. Since we are searching for the fixed point solution of the master equation, we keep only the leading order in $\Omega$ of Eq. (12). This yields for $\Omega \to 0$ the necessary condition

$$\mu'(\Omega) = 0. \quad (13)$$

Thus, the solution approaches for $\Omega \to 0$ a fixed point with vanishing slope of the dynamical exponent.

The fixed point value $\Gamma(\Omega = 0) = 1/\mu(\Omega = 0) = \Gamma_0$ is finite, but cannot be determined by this calculation alone. To this end we need to use a scaling argument, as outlined below. The distribution of lengths $l$ of singlets at renormalization scale $\Omega$ can also be derived from a master equation, as was done in Ref.10,19 for the IRFP. However, noting that the strong disorder fixed point distribution $P(J, \Omega)$ was obtained above to lowest order in a Taylor expansion in the difference between the renormalized and the bare coupling $J^0(l) = J_0(l/a)^{\alpha}$, it is clear that there is a strong correlation between the distribution of lengths and bare couplings. Therefore, we can make to lowest order the ansatz,

$$P(J, \Omega, l) = P(J, \Omega) \delta(J - J_0(l/a)^{\alpha}) \frac{dJ_0(l/a)^{\alpha}}{dl}. \quad (14)$$

We note that in each RG step, a fraction $dn/n(\Omega)$ of the remaining spins $n(\Omega)$ at renormalization energy $\Omega$ are taken away. Since this is due to the formation of a singlet with coupling $J = \Omega$, this fraction should be equal to $2P(J = \Omega, \Omega)\Omega$, leading to the differential equation

$$\frac{dn}{d\Omega} = 2P(J = \Omega, \Omega)n(\Omega). \quad (15)$$

Since at the SDFP $P(J = \Omega, \Omega) = \mu/\Omega$, the density of not yet decimated singlets at the RG scale $\Omega$ is given by

$$n(\Omega) = n_0 \left(\frac{\Omega}{\Omega_0}\right)^{2\mu} \quad (16)$$

where $n_0 = N/L = 1/l_0$ is the initial density of spins. Defining $l_\Omega$ as the average distance between spins at RG scale $\Omega$, we have $n(\Omega) = 1/l_\Omega$. Thus, it follows from Eq. (16) that the RG energy scale is related to the length $l_\Omega$ via $\Omega \sim (\frac{1}{l_\Omega})^\alpha$. As we discussed above, the strong disorder fixed point distribution is dominated by the bare couplings, which scale with distance $l$ as $J^0(l) \sim l^{-\alpha}$. In order for the energy-length scaling to be consistent at all RG scales $\Omega$, it follows necessarily that

$$2\mu = 1/\alpha. \quad (17)$$

As we have shown above by solution of the master equation that the strong disorder fixed point distribution is a solution for $\mu < 1$, we can conclude that it is expected to give consistent results for $\alpha > 1/2$.

We are now ready to evaluate the distribution of singlet lengths by integrating over the renormalization energy $\Omega$

$$P_s(l) = 2 \int_{\Omega_0}^{\Omega} d\Omega_0 n(\Omega) P(J = \Omega, l; \Omega), \quad (18)$$

where we have used the fact that $n(\Omega)$ is the fraction of not yet decimated spins at $\Omega$, and the factor 2 comes from the normalization condition for $P_s(l)$, and $\Omega^* = J_0((L - 1)/a)^{-\alpha}$ is the smallest possible energy scale. Thus, for $L \to \infty$ we find

$$P_s(l) = \int_{0}^{\Omega_0} \frac{d\Omega}{\Omega} \left(\frac{\Omega}{\Omega_0}\right)^{2\mu} \delta(\Omega - J_0 \frac{\alpha}{\Omega}) J_0 \frac{\alpha}{\Omega^{\alpha+1}} = \frac{a}{l^\alpha}. \quad (19)$$

Here we used $\mu = 1/(2\alpha)$ and the fact that $\Omega_0 = J_0$ is the largest energy scale. So far, we have assumed that $l$
can take any value within the interval \([a, L]\). Taking into account that the distance can in fact only take discrete values \(l_i = ia\), the properly normalized probability mass function \(p_i\) for \(L/a \to \infty\) would be \(p_i = 6/(\pi^2 i^2)\). However, as the renormalization of the couplings will become more important as the RG scale \(\Omega\) is lowered, corresponding to intermediate and long length scales \(l\), let us check the actual distribution in that regime, by numerical implementation of the SDRG. In Fig. 5 we show results for \(N = 200\) spins, \(\alpha = 1.8\) and \(\alpha = 4.8\) and various filling factors \(\frac{L}{N} = 0.2, 0.1, 0.04\). We find that the prefactor scales with the inverse density, the average spacing between the spins \(l_0 = L/N\) as

\[
P(l_s) \approx \frac{L}{3N^2} l_s^{-2}, \quad \text{for } a \ll l_s \ll L, \tag{20}
\]

for both \(\alpha = 1.8\) and \(\alpha = 4.8\) in the intermediate scaling regime. We find a drop off at small \(l_s < l_0 = L/N\), and a slower decay for large \(l_s \to L\). Note that the numerical \(P(l_s)\) is properly normalized, when summing over all \(l_s \in [a, L-a]\).

![FIG. 5. Probability distribution of singlet lengths \(P(l_s)\), where \(l_s\) is the real physical distance, on a logarithmic scale, obtained via SDRG for \(N = 200\) and for various filling factors \(N/L = 0.2, 0.1, 0.04\). The data were generated for \(10^5\) disorder realizations with fixed \(\alpha = 1.8\) (a) and \(\alpha = 4.8\) (b). Red dashed lines: function \(\frac{L}{3N^2} l_s^{-2}\), fitting the intermediate \(a \ll l_s \ll L\) scaling regime.](image)

### III. CONCURRENCE

The entanglement between any two spins of a chain can be quantified by the concurrence between them\(^{20}\). When the spins in the chain are in a pure state, \(|\psi\rangle\), such as the RS state, the concurrence between spins \(m\) and \(n\) is given by the correlation function

\[
C_{mn} = |\langle \psi | \sigma_m^y \sigma_n^y | \psi \rangle|, \tag{21}
\]

which is the absolute value of the overlap between the original state and the state obtained after spins \(m\) and \(n\) have been flipped. As reviewed above, the SDRG procedure yields a random singlet state (RSS) as an approximation of the ground state of the system, even when long-range couplings are present. The RSS is known to become asymptotically exact for short-range models, characterized by the infinite randomness fixed point (IRFP)\(^5\). This RSS is a product state that can be written in the form

\[
|\psi_{RS}\rangle = \bigotimes_{(i,j) \in RS} |0_{ij}\rangle, \tag{22}
\]

where \(|0_{ij}\rangle = (|\uparrow_i \downarrow_j\rangle - |\downarrow_i \uparrow_j\rangle) / \sqrt{2}\) is the singlet state between spins enumerated by \(i\) and \(j\), and the direct product extends over all singlets forming the RSS. From Eq. (22) it becomes apparent that when the system is in the RSS, the concurrence between the two spins \(i, j\) is given by

\[
C_{ij} = \begin{cases} 
1 & \text{if } i \text{ and } j \text{ form a singlet in the RSS}, \\
0 & \text{otherwise}. 
\end{cases} \tag{23}
\]

Thus, as the RSS disregards any but the strongest couplings, it fails to account for corrections by residual weak couplings. In order to include the finite amount of entanglement which prevails between spins that do not form a singlet in the RSS, and in turn weakens the entanglement between the spins that do form a singlet during the SDRG procedure, we need to find a consistent strategy to include these corrections in the SDRG scheme.

Before proceeding any further, let us first review the known results for the scaling behavior of the mean and typical concurrence at the IRFP, i.e. the fixed point for short-range coupled random spin chains, which will serve as a baseline to compare with results obtained in the SDFP.

### IV. MEAN AND TYPICAL CONCURRENCE AT THE IRFP

As Fisher noted in Ref.\(^6\), the mean correlation function between spins at long distances \(l\) is dominated by rare events. Typically, two distant spins enumerated by indices \(n_1\) and \(n_2 = n_1 + n\) will not form a singlet and will therefore be very weakly correlated. However, in the rare
event that they do form a singlet in the RSS, they will be strongly correlated and therefore will dominate the mean correlation function, and thereby the concurrence, at large distances. As a result, the mean correlation function must be proportional to the ratio of singlets formed at index distance \( n \), \( P(n) \), which is related to the distribution function of real distances \( l \), \( P(l) \), which we have reviewed above. At the IRFP, \( P(l) \sim \alpha / l^2 \), and we see that the mean correlations decay faster when disorder is introduced: in the clean case they decay more slowly as \( l^{-1/2} \).

Hayos et al. explicitly noted that for chains with open boundary conditions \( C(n) = 0 \) for even index distance \( n \), which yields the more accurate result at the IRFP \(^{10,21}\),

\[
C(n) \sim \frac{1}{n^2} \times \begin{cases} 
1 & \text{if } n \text{ is odd}, \\
0 & \text{if } n \text{ is even}. 
\end{cases} \tag{24}
\]

It was also noted in Ref. \(^{10}\) that there are additional terms in \( C(n) \) that decay faster for large \( n \), the next leading term decaying as \( 1/n^{5/2} \). While rare events dominate the mean concurrence, we expect a different behavior for the typical concurrence which is proportional to the typical value of the coupling between two spins \( J \) at the RG scale \( \Omega_t \) at which they are decimated. This value can be calculated using the full IRFP distribution of \( J \). Thereby, one finds \(^{6,10}\),

\[
C_{\text{typ}}(l) \sim e^{-k \sqrt{l}}, \tag{25}
\]

where it was used that at the IRFP the distance between spins is related to the RG scale \( \Omega_t \) by \( l \sim \ln^2(\Omega_0 / \Omega_t) \) to obtain the scaling behavior as an extended exponential, with \( k \) being a non-universal constant of order unity \(^6\). Thus, at the IRFP the typical value of the concurrence decays exponentially fast with distance, whereas its mean decays with a power law. In the next section we introduce a general approach to include corrections to the RSS state, and we will, in particular, investigate how the typical concurrence decays with \( l \) at the SDFP.

V. CORRECTIONS TO THE RANDOM SINGLET STATE

To incorporate the effects of the couplings which are neglected in the RSS state we define an effective Hamiltonian as the sum of the Hamiltonian \( \hat{H}_0 \) with all effective, renormalized couplings taken into account in the SDRG, and a perturbation term \( \hat{H}' \), which includes all couplings which are neglected in the SDRG,

\[
\hat{H} = \sum_{\{ij\} \in \text{RS}} \hat{J}_{ij} S_i S_j + \sum_{\{ij\} \notin \text{RS}} \hat{J}^{\prime}_{ij} S_i S_j + \hat{H}_0 \tag{26}
\]

Now, we can perform perturbation theory in the term \( \hat{H}' \) to obtain the ground state of the disordered XX chain in first order of \( \hat{H}' \) as,

\[
|\psi \rangle = |\psi_{RS} \rangle + \sum_{\beta} \frac{\langle \psi_{\beta} | \hat{H}' | \psi_{RS} \rangle}{E_{RS} - E_{\beta}} |\psi_{\beta} \rangle, \tag{27}
\]

where \( E_{RS} \) is the ground state energy of the RS state \( |\psi_{RS} \rangle \), and the sum runs over all excited states of \( H_0 \), \( |\psi_{\beta} \rangle \), as labeled by the index \( \beta \), with eigen energies \( E_{\beta} \). The excited states can be obtained by combinations of triplet states, as obtained by excitations of the singlets in the RS state. We note the useful relation

\[
\hat{H}' |\psi_{RS} \rangle = \frac{1}{4} \sum_{\{nl\} \neq \{mk\}} (J_{nm} + J_{lk} - J_{nk} - J_{ml}) \times

(|+nl\rangle |−mk\rangle + |−nl\rangle |+mk\rangle) \bigotimes_{\{ij\} \neq \{nl\}} |0_{ij} \rangle, \tag{28}
\]

where \( |\pm nl \rangle \equiv |(S = 1, M = \pm 1)\rangle \) are two of the triplet states formed of the spins \( \{l, n\} \) when the spins \( l \) and \( n \) form a singlet in the RSS. Thus, the double sum and the direct product run over all singlet pairs in the RSS, with the exceptions specified under the summation and direct product signs \(^{22}\). From this result, it becomes apparent that the only excited states that contribute to the sum in Eq. \((27)\) are of the form

\[
|\psi_{\beta} \rangle = |\pm nl \rangle |\mp mk \rangle \bigotimes_{\{ij\} \neq \{nl\}} |0_{ij} \rangle, \tag{29}
\]

whose energy difference to the RS state is given by \( E_{\beta} - E_{RS} = (J_{nl} + J_{mk})/2 \). With this in mind, Eq. \((27)\) transforms into the final form of the ground state with corrections,

\[
|\psi \rangle = c_\psi |\psi_{RS} \rangle - c_\psi \frac{J_{nl} + J_{mk}}{2} \sum_{\{nl\} \neq \{mk\}} (|+nl\rangle |−mk\rangle + |−nl\rangle |+mk\rangle) \bigotimes_{\{ij\} \neq \{nl\}} |0_{ij} \rangle, \tag{30}
\]
with a normalization constant $c_\psi$ given by

$$c_\psi = \left(1 + \frac{1}{2} \sum_{\{ml\} \neq \{mk\}} \left( \frac{J_{nm} + J_{lk} - J_{nk} - J_{ml}}{J_{nl} + J_{mk}} \right)^2 \right)^{-1/2}.$$  \tag{31}

Now, we are all set, and we can use the perturbed ground state, given by Eq. (30), to derive the concurrence between the spins with indices $p$ and $q$. We find the conditional expression

$$C_{pq}^{NS} = c_\psi \left| J_{pq} + J_{rs} - J_{pr} - J_{qs} \right| \frac{J_{ps} + J_{qr}}{J_{pq} + J_{sr}} \quad \text{if } \{pq\} \notin RS,$$

$$C_{pq}^S = 1 - \frac{c_\psi}{2} \sum_{\{mk\} \neq \{pq\}} \left( \frac{J_{pm} + J_{gk} - J_{pk} - J_{mg}}{J_{pq} + J_{mk}} \right)^2 \quad \text{if } \{pq\} \in RS,$$  \tag{32}

where $C_{pq}^{NS}$ is the concurrence between spins $p$ and $q$ if they do not form a singlet in the RS state, and $C_{pq}^S$ is the one, if they do. The indexes $r$ and $s$ in the first line correspond to the spins that form a singlet in the RS state with spins $q$ and $p$, respectively, as shown in Fig. 6.

Eq. (32) has all the properties expected for the concurrence between two spins in a chain with long-range couplings. It does give a non-zero value for all pairs that do not form a singlet in the RS state, and it gives a concurrence smaller than 1 for spins that do.

In Fig. 7(a) we show numerical results for the mean concurrence as a function of index distance $n$ in the disordered long-range XX chain with $N = 800$ spins randomly placed on $L = 80000$ sites, as obtained by inserting the numerical results of the SDRG for the couplings into Eq. (32). First, we note that, in contrast with the short-range case, there is a finite concurrence for even values of $n$. This is expected by looking at the form of Eq. (32) and recalling that $C(n) = 0$ for even $n$ was due to the impossibility of crossing singlets in the RS state. However, there is still a clear difference between even values of $n$ (bottom) and odd ones (top), as indicated by the clear separation of two sets of curves. Both sets of curves have a weak dependence on $\alpha$ and a regime in which it can be fitted with a power law,

$$\tilde{C}(n) \sim n^{-\gamma_{e,o}},$$  \tag{33}

where $\gamma_{e,o}$ are the decay powers for even and odd values of $l$, respectively. In fact, by using linear regression fits in the logarithmic scale we find $\gamma_e = 1.75 \pm 0.04$ and $\gamma_o = 1.95 \pm 0.04$ for both $\alpha = 0.6$ and $\alpha = 2.0$. Even with the corrections to the RS state the concurrence for odd values of $n$ is still dominated by rare events (singlets formed at long distances), as indicated by the small deviation from $C(n) \sim n^{-2}$ decay for all values of $\alpha$. On the other hand, for even values of $n$, the decay is slower, the power-law regime is smaller, and the amplitudes have a stronger dependence on $\alpha$, as expected from Eq. (32). For both sets of curves, a saturation at large values of $n$ can be seen, which is a finite size effect.

The typical value of the concurrence is shown in Fig. 7(b). A clear power-law behavior of the form

$$C_{typ}(n) = \exp((\ln C(n))) \sim n^{-\gamma(\alpha)},$$  \tag{34}

is found. Here, the power $\gamma(\alpha)$ has a strong dependence on $\alpha$, unlike the decay powers of the mean value. In fact, we find $\gamma(\alpha)$ to be linear in $\alpha$, with a linear regression fit.
which indicates that the typical concurrence decays faster than the mean concurrence for all values of $\alpha$. It is also worth noting that since the typical concurrence decays as a power law, it decays slower than in the IRFP case, where it has the extended exponential behavior stated in Eq. (25).

Now, let us see if we can use the corrections to the RS state, Eq. (32) to find the scaling behavior of the typical concurrence analytically. The probability mass function as a function of the index distance $n$ decays to leading order as $1/n^s$, in accordance with the distribution of lengths, Eq. (20). Thus, noting that in the random singlet state only spins at odd index distance are paired we find

$$P(n) = \left(c_2 \frac{1}{n^2} + O\left(\frac{1}{n^{5/2}}\right)\right) \times \begin{cases} 1 & \text{if } n \text{ is odd}, \\ 0 & \text{if } n \text{ is even}. \end{cases}$$  \hspace{1cm} \text{(36)}$$

Since $P(n)$ must be normalized, $\sum_{n=1}^{N} P(n) = 1$, the coefficient $c_2$ depends on the weight of the faster decaying terms. In Ref. $^10_1$, $c_2 = 2/3$ was derived for the IRFP of the short ranged disordered AFM spin chain. In Fig. 8 we show histograms of the index singlet length distribution $P(n_s)$ on a logarithmic scale, obtained using the SDRG for $N=400$ with a filling factor $\frac{N}{L} = 0.1$. The data were obtained from 25000 realizations of the disorder for every $\alpha$. The red dashed line corresponds to the function $\frac{2}{3}n_s^{-2}$, showing good agreement for intermediate and large values of $n_s$, in agreement with Eq. (36) with $c_2 = 2/3$. We also observe deviations due to a faster decaying term at small $n$, in agreement with Eq. (36). The saturation at large values of $n$ has been checked to be a finite size effect.

Now, we can calculate the mean value of the concurrence as a function of index distance $n$ via

$$\bar{C}(n) = \langle C_{pq} \rangle_{n=|p-q|} = P(n)C^S_{pq} + (1-P(n))C^{NS}_{pq},$$ \hspace{1cm} \text{(37)}$$

and the typical value of the concurrence via

$$C_{typ}(n) = \exp \left( P(n) \ln C^S_{pq} + (1-P(n)) \ln C^{NS}_{pq} \right).$$ \hspace{1cm} \text{(38)}$$

We note that in the random singlet state without corrections, Eq. (37) gives with Eq. (36)

$$C^{RSS}(n) = \left(c_2 \frac{1}{n^2} + O\left(\frac{1}{n^{5/2}}\right)\right) \times \begin{cases} 1 & \text{if } n \text{ is odd}, \\ 0 & \text{if } n \text{ is even}, \end{cases}$$ \hspace{1cm} \text{(39)}$$

when properly normalized, so that $\sum_{n=1}^{\infty} C^{RSS}(n) = 1$, since each spin can form a singlet with only one other spin, in which case the concurrence is exactly equal to one, giving $c_2 = 2/3$. Now, we can find the scaling of $C^{NS}_{pq}$ including the corrections to the RSS by noting that the distance $l = |r_p - r_q|$ is always larger than the distance between the spins which formed singlets in the RS state, see Fig. 6 top, $l_1 = |r_p - r_q|$, $n_2 = |r_q - r_r|$. Thus, we can Taylor expand Eq. (32) in $l_1/l$ and $l_2/l$. Thereby we find

$$C^{NS}_{pq} = c_2^2 \frac{l_1l_2}{J_{l_1} + J_{l_2}} \alpha \frac{\psi_0}{\psi_0 - 1} \ln \frac{\psi_0}{\psi_0 - 1} \frac{\psi_0 - 1}{\psi_0 + 1} \frac{l_1l_2}{l_1^{\alpha} + l_2^{\alpha} l^{-\alpha-2}}.$$ \hspace{1cm} \text{(40)}$$

Noting that at the SDRG $J_l = J_0(l)^{-\alpha}$ can be related to the index distance $n$ by assuming that $l$ scales with $n$ as dictated by the density of spins $n_0 = 1/l_0$, we can substitute $l \sim n l_0$. As the bonding lengths $l_1$ and $l_2$ can take any value between 1 and $l$, we can average over all possible values and find as function of index distance $C^{NS}_{pq} = k^{NS} n^{-\alpha-2}$, with a constant $k^{NS}$.

Similarly, we can do an expansion $C^S_{pq}$ in the distance between the spins of the singlet states in Fig. 6 bottom $l = |l_p - l_q|$ and $l_2 = |l_k - l_m|$ to find

$$C^S_{pq} = 1 + c_2^2 \frac{\alpha}{4(\alpha + 1)} l^{1-\alpha}.$$ \hspace{1cm} \text{(41)}$$

Thus, we can insert Eqs. (40,41) into Eqs. (37,38) to get the scaling of the mean and typical concurrence with index distance $n$

$$\bar{C}(n) = P(n)(1 + c_2^2 \frac{\alpha}{4(\alpha + 1)} (nl_0)^{1-\alpha})$$

$$+ (1-P(n))k^{NS} n^{-\alpha-2},$$ \hspace{1cm} \text{(42)}$$

and the typical value of the concurrence by

$$C_{typ}(n) = (k^{NS} (nl_0)^{-\alpha-2})^{1-P(n)} (1 + c_2^2 \frac{\alpha}{4(\alpha + 1)} (nl_0)^{1-\alpha}) P(n) \sim n^{-\alpha-2},$$ \hspace{1cm} \text{(43)}$$

FIG. 8. Probability distribution of the singlet lengths, $P(n_s)$, as a function of index distance, on a logarithmic scale, obtained via the SDRG for $N=400$ and a filling factor $\frac{N}{L} = 0.1$. The data were obtained using 25000 realizations of the disorder for every $\alpha$. The red dashed line corresponds to the function $\frac{2}{3}n_s^{-2}$, which fits the intermediate $n_s$ scaling regime.
where we used that $P(n) \ll 1$. For the typical value we thus find very good agreement of the power $\gamma = 2+\alpha$ with the result obtained with numerical SDRG for system size, Eq. (35), $\gamma(\alpha) = 1.02\,\alpha + 2.02$. The mean value shows a more complicated behavior with different index distance regimes dominated by either $P(n)$ or the power law decay in Eq. (42).

When plotting the concurrence as function of physical distance $l$, we expect for small concentrations of spins $N/L \ll 1$ no even-odd effect. As we have numerically derived above $P(l) = c^2 l^{-2} + O(l^{-5/2})$, Eq. (20) where it was found that $c^2 = 1/3$. Thus, we get the average concurrence as function of real distance $l$,

$$\bar{C}(l) = P(l)(1 + c^2\frac{\alpha}{4(\alpha + 1)}l^{1-\alpha}) + (1 - P(l))k^{NSl^{-\alpha-2}},$$

and the typical value of the concurrence as function of the physical distance $l$ is

$$C_{\text{typ}}(l) = (k^{NSl^{-\alpha-2}})^{1-P(l)}(1 + c^2\frac{\alpha}{4(\alpha + 1)}l^{1-\alpha})^{P(l)} \sim l^{-\alpha-2},$$

For comparison we show in Fig. 9 the results of numerical exact diagonalization for spin chains with $N=20$ distributed randomly of length $L = 200$, as plotted as function of the physical distance $l$ and averaged over $M = 2000$ samples. We find that the average concurrence decays with a power which increases slightly with increasing interaction power $\alpha$ but remains for all $\alpha$ smaller than the power 2, obtained in SDRG. Also, there is no even odd effect, as expected when plotting the concurrence as function of the physical distance $l$. The typical concurrence is found to decay with a power law, with exponent $\gamma = 0.21\alpha + 1.09$, as obtained by a fit of all results for $\alpha = 0.8, 1.0, 1.2, 1.6, 2.0, 2.8$, linearly increasing with $\alpha$ as found from SDRG, but with a smaller slope. Note that the finite size effects seen in SDRG, Fig. 7 are expected to be more dominant in the smaller size used in ED as presented in Fig. 9, which may explain the slower decay with smaller exponents observed with ED.

VI. ENTANGLEMENT ENTROPY

The entanglement between two segments of a spin chain, $A$ and $B$, can be quantified by the von Neumann entropy of the reduced density matrix,

$$S = -\text{Tr}(\rho_A \ln \rho_A) = -\text{Tr}(\rho_B \ln \rho_B),$$

where $\rho_A = \text{Tr}_B(|\psi\rangle \langle \psi|)$ and $\rho_B = \text{Tr}_A(|\psi\rangle \langle \psi|)$ is obtained by partially tracing the complete density matrix of the system over all degrees of freedom of subchain $B$ or $A$, respectively.

This entanglement entropy can be used to characterize quantum phase transitions. For clean chains, it has been shown that at criticality, the entropy of a subchain $A$ of length $l$ scales as

$$S(l) \propto \frac{b\,c + \tau}{2 - 6\ln(l/a)} + k,$$

where $c$ and $\tau$ correspond to the central charges of the corresponding 1+1 conformal field theory. In the limit of infinite chains with finite partitions of length $l$, as well as for periodic chains with large length $L \gg l$, $b = 2$ since there are two boundaries of the partition, while $b = 1$ for semi infinite chains, when the partition of length $l$ is placed on one side of the chain. $k$ is a non-universal constant. This scaling behavior with a logarithmic dependence on the segment length $l$ is in contrast to the area law expected for noncritical chains, where it does not depend on the length $l$ of the subchain for the one-dimensional case. The simple area law is recovered away from criticality, where it is found that the entropy saturates at large $l$.

FIG. 9. Results from exact numerical exact diagonalization. Panel (a): Mean concurrence of disordered XX chains with power-law, long-ranged couplings, averaged over $M = 2000$ number of realizations as function of the physical distance $l$ for various power exponents $\alpha$, $N = L/10 = 20$ spins placed randomly on one of $L$ sites. Panel (b): typical concurrence as a function of the physical distance $l$. Inset: Fits of linear regime in the typical concurrence to a power-law decay with power $\gamma$. The fitted exponents $\gamma$ are plotted as a function of $\alpha$. 
In Ref.\textsuperscript{9}, it was shown that Eq. (47) also holds for the average entanglement entropy of antiferromagnetic spin chains with random short-ranged interactions. In particular, using SDRG, they found that in the disordered transverse Ising Model, the effective central charges were given by $c = \overline{c} = \ln(2)/2$, whereas in the Heisenberg and XX model $c = \overline{c} = \ln(2)$. Both cases correspond to a factor of $\ln(2)$ reduction of the central charge and the entanglement entropy of their corresponding pure systems\textsuperscript{24}, in accordance with a generalized $\overline{c}$-theorem, which states that if two critical points are connected by a relevant RG flow, as here induced by the relevant disorder, the final critical point has a lower conformal charge than the initial one\textsuperscript{9}.

Eq. (47) applies specifically to infinite systems. In Ref.\textsuperscript{8}, Calabrese and Cardy derived a formula valid for finite systems of length $L$,

$$S_b(l) = \frac{b}{6} c \ln \left( \frac{L}{\pi a} \sin(\pi l/L) \right) + k', \quad (48)$$

where $k'$ is a non-universal constant, and $c = \overline{c}$ has been assumed\textsuperscript{8}. For periodic boundary conditions, there is an additional factor $b = 2$, since the subsystem is then bounded by two boundaries, doubling the average number of singlets crossing one of the boundaries, while $b = 1$ for open boundary conditions, when there are 2 partitions.

Refael and Moore’s method to calculate the average entanglement entropy in the presence of disorder is based on the assumption that the system has been drawn to the IRFP, and the random singlet state (RSS) is a correct representation of its ground state. Since the RSS corresponds to a product state of maximally entangled spin pairs, they note that the total entanglement entropy can be calculated by counting the number of singlets that cross the boundary between subsystems $A$ and $B$ and then multiplying this number with the entropy of a singlet $S_0 = \ln(2)$\textsuperscript{9,10}. A schematic representation of this method is shown in Fig. 10 for a specific realization. In this example, when the boundary between $A$ and $B$ is defined by line $a$, we obtain an entanglement entropy of $3 \cdot S_0$, since three singlets cross over the boundary line. But if the boundary is defined by line $b$, the entanglement entropy is reduced to $1 \cdot S_0$.

![FIG. 10. Single realization of the random singlet state, illustrating the entanglement entropy calculation for two different boundaries $a$, $b$ (red lines) between subsystems.](image)

Thus, for the random singlet state $|\psi_0\rangle$ one finds $S = M \ln 2$, where $M$ is the number of singlets which cross the partition between subsystems $A$ and $B$. The average entanglement entropy of a random singlet state can therefore be related to the probability to find a singlet of a certain length $n_s$, in the spin chain of length $N$\textsuperscript{9,10}, $P(n)$. As Refael notes in Ref.\textsuperscript{9}, however, one needs to take into account the correlation with the RG history. He found that the average distance between RG steps, where a decimated singlet may cross the same partition, is exactly equal to $(m) = 3$ for the disordered nearest neighbor AFM spin chain, resulting in a correlation factor $1/(m)$.

Another way to derive this was outlined by Hoyos et al. in Ref.\textsuperscript{9,10}. The ratio of the number of singlets crossing the partition is the probability that a spin on one side of the partition is entangled with another one on the other side of the partition. Thus, we can relate the entanglement entropy directly to the probability to have a singlet of length $l$, $P(l)$, which we derived in the previous chapter. Moreover, as we consider partial filling of the lattice sites with spins with density $n_0 = N/L < 1$, we need to distinguish the EE as a function of the index distances $n = |i - j|$ between the spins from the one plotted as function of their physical distance $l = r_i - r_j$, where $r_i$ is the position of spin $i$. As a function of index distance $n$ we obtain for open boundary conditions and 2 partitions, where one has the length $l$, the average entanglement entropy,

$$\langle S_n \rangle = \ln 2 \sum_{n_s=1}^{N} \sum_{i} P(n_s)|c.c., \quad (49)$$

where the crossing condition (C.C.) ensures that only singlets are counted where spin $i$ is on the left side of the partition (which contains $n$ spins), while spin $i + n_s$ is on the right side of the partition. We first count the number of possible positions to place a singlet with index distance $n_s$ across the partition boundary, starting with the smallest distance $n_s = 1$, and adding successively singlets of larger index length. For $n_s < n$ there are, in principle, $n_s$ such possibilities, if the respective spins did not yet form a singlet with another spin, each with the probability to form a singlet of length $n_s$, $P(n_s)$.

In order to account for the correlation with existing singlets, Ref.\textsuperscript{10} multiplied the probability $P(n_s)$ with a factor $1/2$. This can be argued to be due to the fact that for every spin which may form a singlet with length $n_s$ across the boundary there is a second possibility to form a singlet, which is not crossing the boundary. Thereby, one arrives for the chain with OBC with a partition with $n$ spins and one partition boundary at the following ex-
expression

\[ \langle S_n \rangle / \ln 2 = \frac{1}{2} \sum_{n_x=1}^{n} n_x P(n_x) + \frac{1}{2} n \sum_{n_x=n+1}^{N-n} P(n_x) + \frac{1}{2} \sum_{n_x=N-n+1}^{N} (N-n_x)P(n_x). \]  

(50)

This expression is equivalent to the one given in Ref.\textsuperscript{10} (with the difference that they considered an embedded partition with two boundaries). By evaluating Eq. (50) using the result Eq. (39) \[ P(n) = c_2/n^2 + O(1/n^{5/2}) \] for odd \( n \), 0 for even \( n \) we find in the limit of \( N \gg 1 \)

\[ \langle S_n \rangle \approx \frac{1}{4} c_2 \ln 2 \ln n + k + O(1/n^{1/2}). \]  

(51)

We thus recover by comparison with Eq. (47) the conformal charge given by \( \tilde{c} = \tilde{c} = (6/4) c_2 \ln 2 \). Using \( c_2 = 2/3 \), as derived in Ref.\textsuperscript{10} and confirmed numerically above, we thus find \( \tilde{c} = \ln 2 \) in agreement with\textsuperscript{9,10}.

For finite \( N \) we can do the summations, written in terms of Polygamma functions as function of \( n \) :

\[ \langle S_n \rangle = \frac{2 \ln 2}{<m>_{\pi^2}(2\gamma - 4/3 - n + N) + \ln 16 + 2PG[0,3/2 + (n-1)/2] - 2PG[0,3/2 + (N-1)/2] + 2PG[0,5/2 + (n-1)/2 + (N-1)/2] + n PG[1,3/2 + (n-1)/2] - N PG[1,3/2 + (N-1)/2] + (N-n)PG[1,3/2 - (n-1)/2 + (N-1)/2]) \]  

(52)

where \( \gamma = \text{EulerGamma} = 0.577 \), and \( PG[x,y] = \text{PolyGamma}[x,y] \) is the PolyGamma function.

In an attempt to take into account the correlation with the location of other singlets in the RSS state more rigorously, we could argue that we need to multiply each term with the probability that the two spins did not yet form a singlet of other length with another spin, that is \( \prod_{n_x \neq n_x'} (1-P(n_x')) \). Thereby, one finds for a random singlet state, using Eq. (39)

\[ \langle S_n \rangle / \ln 2 = \sum_{n_x=1}^{n} n_x P(n_x) \prod_{n_x'} (1-P(n_x')) + n \sum_{n_x=n+1}^{N-n} P(n_x) \prod_{n_x'} (1-P(n_x')) + \sum_{n_x=N-n+1}^{N} (N-n_x)P(n_x) \prod_{n_x'} (1-P(n_x')). \]  

(53)

By evaluating Eq. (53) we find in the limit of \( N \gg 1 \)

\[ \langle S_n \rangle \approx \frac{1}{6} c_2 \ln 2 \ln n + k + O(1/n^{1/2}). \]  

(54)

We thus recover Eq. (47) with the conformal charge given by \( \tilde{c} = \tilde{c} = c_2 \ln 2 < 1 \). Here, for pure \( P(n) = c_2/n^2 \) for odd \( n \), \( P(n) = 0 \) for even \( n \) we have \( c_2 = 8/\pi^2 = 0.81 \). If there are faster decaying correction terms \( O(1/n^{5/2}) \), Eq. (39), as is confirmed by our numerical results we get \( c = c_2 \ln 2 = 2/3 \ln 2 \), smaller by a factor 2/3 than found previously.

We can also derive the EE as function of the physical distance \( l \). For small filling, \( N \ll L \), the even odd effect as function of the physical distance \( l \) is negligible and we get for intermediate range \( a \ll l \ll L \), Eq. (20), as confirmed numerically. We thus recover Eq. (47) with the central charge given by \( \tilde{c} = \tilde{c} = c' \ln 2 < 1 \). Here, using Eq. (20) we get \( c' = 1 \).

Let us next implement the SDRG numerically. Fig. 11 shows results, numerically calculating the mean block entanglement entropy using Refael and Moore’s prescription illustrated in Fig. 10, which is plotted as function of the index distance \( n \) of the partition, that counts how many spins are inside a partition. The XX chain with open boundary conditions has \( N = 500 \) spins with long-range power-law interactions Eq. (2). As mentioned above, such a prescription implies that the RSS is a good approximation of the actual ground state of the chain.

The result for the average entanglement entropy as function of index distance \( n \) is shown in Fig. 11 for various values of \( \alpha \) with open boundary conditions. The blue line is Eq. (48) with a central charge \( c = \ln(2) \), \( b = 1 \) and \( k' = 0.18 \).

We thereby find that the EE is in good agreement with Eq. (48), and we observe only a weak dependence on \( \alpha \), decaying by only a few percent as \( \alpha \) is changed from \( \alpha = 6 \) to \( \alpha = 0.8 \).

In Fig. 12 we plot the average block entanglement entropy as function of the physical distance \( l \) for the long ranged XX-chain with \( N = 500 \) spins, open boundary conditions for various values of \( \alpha \), and for a filling factor \( \frac{N}{L} = 0.1 \). The average was evaluated over 20000 realizations for each \( \alpha \). The blue dashed line corresponds to the Cardy law Eq. (48) with \( b = 1 \), \( k' = 0.05 \) and a central charge \( c = \ln(2) \), in very good agreement with the analytical result \( c = \ln(2) \). In Fig. 13 the average block entanglement entropy as function of partition length \( l \) is shown, as obtained with numerical SDRG for the long ranged XX-chain with \( N = 200 \) spins, and for various filling factors \( \frac{N}{L} = 0.2,0.1,0.04 \), with open boundary conditions and for two values of \( \alpha \). The average was evaluated over \( M = 100000 \) realizations for each \( \alpha \). The dashed lines correspond to the Cardy law Eq. (48) with a central charge \( c = \ln(2) \), \( b = 1 \), in good agreement with the analytical result.

As both analytical and numerical results based on SDRG could be artefacts of the assumption that the ground state remains a random singlet state, let us next calculate the entanglement entropy using the numerical exact diagonalization method. In Figs. 14 and 15 we show the results for the average block entanglement entropy, obtained by numerical exact diagonalization for the long ranged XX-chain for a filling factor \( \frac{N}{L} = 0.1 \) with open boundary conditions, in Fig. 14 for
of a clean critical spin chain a wide range of \( c \) is explained by the \( L/2 = 0.13 \) for \( l \), corresponding to the approximation of the Cardy law Eq. (47) for \( l \ll L \) with a central charge \( c = 1 \). The yellow line is Eq. (47) with \( c = \ln 2 \), corresponding to the result obtained with SDRG. We see that while for a wide range of \( l \), the central charge seems to fit to the one of a clean critical spin chain \( c = 1 \), at small \( l \) there are strong deviations tending rather to the SDRG result.

As the averaging may diminish the dependence on \( \alpha \), let us next also consider the full distribution of the entanglement entropy for (a) \( \alpha = 0.1 \), (b) \( \alpha = 0.8 \) and (c) \( \alpha = 2.8 \), where 500 random samples have been taken, and the system size \( N = 22 \) is used, and \( S_\alpha^0 = \log 2 \). We note that also the distribution shows only a weak dependence on \( \alpha \). It is remarkable that the distribution is peaked at integer multiples of \( \ln 2 \), which means that even when averaged over many ensembles, an integer number of singlets crossing the partition is most likely.

![FIG. 11. Average block entanglement entropy as obtained with the numerical SDRG for the long ranged XX-chain with \( N = 500 \) spins, open boundary conditions, and various values of \( \alpha \) as function of index distance \( n \). The average was evaluated over \( 2 \times 10^4 \) realizations for each \( \alpha \). The blue line is Eq. (48) with a central charge \( c = \ln(2) \) \( b = 1 \) and \( k' = 0.18 \).](image)

![FIG. 12. Average block entanglement entropy, obtained from the numerical SDRG for the long ranged XX-chain of length \( L = 5000 \), open boundary conditions for various values of \( \alpha \), and for a filling factor \( \frac{N}{L} = 0.1 \) as function of the physical distance \( L \). The average was evaluated over \( 2 \times 10^4 \) realizations for each \( \alpha \). The blue line corresponds to the Cardy law Eq. (48) with a central charge \( c = \ln(2) \), \( b = 1 \) and \( k' = 0.05 \).](image)

VII. ENTANGLEMENT MEASURES OBTAINED BY DENSITY MATRIX RENORMALIZATION GROUP

We consider again the XX model in which \( N \) spins are randomly distributed on a finite lattice with length \( L \) and interact with each other with long-range interactions, but consider also an external Zeeman magnetic field \( B \),

\[
H_{xx} = \sum_{i,j<i} J_{ij}(\alpha, \eta_0) (S_i^x S_j^x + S_i^y S_j^y) - B \sum_i S_i, \quad (55)
\]

where the coupling function is long-range

\[
J_{ij}(\alpha, \xi) = |r_i - r_j|^{-\alpha} \eta_0^{\xi |r_i - r_j|}, \quad (56)
\]

and we introduced an exponential cutoff \( \eta_0 = \exp(-1/\xi) \) with correlation length \( \xi \). Here, the position \( r_i \) is randomly distributed on the chain of length \( L \) with lattice spacing \( a \).

A. DMRG applied to Spin Chains with Power Law Interactions

To find the ground states (GS) of Eq. (55) for different random realizations, we use the density matrix renormalization group (DMRG) method \( 26-28 \) and the noise algorithm \( 29 \) to avoid converging to a local minimum in DMRG calculations. As shown in Ref. 30, DMRG can be regarded as a method for optimizing variational wave functions known as matrix product states (MPS) \( 30,31 \).
which is a representative one-dimensional tensor network state $^3$. In MPS representation, one can rewrite quantum operators in a similar tensor network, so-called the matrix product operator (MPO),

$$\hat{O} = \sum_{\{p_i\}} \sum_{\{\alpha_i\}} O_{\alpha_1p_1}^{\alpha_2p_2} \cdots O_{\alpha_Np_N}^{\alpha_N-1p_{N-1}} |p_1, \cdots, p_N\rangle \langle p_1, \cdots|.$$

(58)

Here, $\{\alpha_i\}$ are the virtual indices which are traced out, and their dimensions are called the bond dimension of MPO. The success of DMRG for one-dimensional systems is due to the existence of an exact MPO representation with finite bond dimensions for a Hamiltonian with short-range or exponentially decaying interactions. For example, the Hamiltonian in Eq. (55) with $\alpha = 0$ and $N = 2.0, 1.0, 2.8$ were considered for both $l = 0$ and $l = 0.4$ were considered for both $\alpha = 0.04$ and $\alpha = 0.2$. The average was evaluated over $M = 2000$ realizations for each $\alpha$. The full lines correspond to the Cardy law Eq. (48) with a central charge $\tilde{c} = 1.4ln(2)$, $b = 1$ and $k' = 0.13$.

$\eta_0 > 0$ can be exactly written in MPO representation with the following tensor

$$O_{\alpha\beta}^{pp'} = \begin{pmatrix} (I)_{pp'} & 0 & 0 & 0 \\ (S_x)_{pp'} & \eta_0(I)_{pp'} & 0 & 0 \\ (S_y)_{pp'} & 0 & \eta_0(I)_{pp'} & 0 \\ B(S_z)_{pp'} (S_x)_{pp'} (S_y)_{pp'} & \zeta(S_z)_{pp'} (I)_{pp'} & 0 & 0 \end{pmatrix}_{\alpha\beta},$$

(59)

where $I$ is the $2 \times 2$ identity matrix. It becomes the nearest neighbor XX-model by setting $\eta_0 = 0$. Unfortunately, an exact MPO expression of a Hamiltonian with the power-law decaying interaction is not allowed with finite bond dimension regardless of its exponent $\alpha$. However, one can decompose the power-law functions into several exponential functions as follows

$$|r_j - r_i|^{-\alpha} \simeq \sum_{l=1}^{m} \lambda_l |r_j - r_i|,$$

(60)

where $m$ depends on the distance $|r_j - r_i|$ and $\alpha$. Finding proper $\{\lambda_l\}$ and $\{\eta_l\}$ is not a trivial problem, but Pirvu et al. in Ref. 33 have found a systematic and elegant way to find them. Employing the fitting procedure in Ref. 33, we have decomposed the power-law function in Eq. (56) into 17 different exponential functions, and they are in excellent agreement with the original power-law function in the range of $\alpha \in [0.2, 2.8]$ on a lattice.
with $L = 800$ ($\alpha \in [0.2, 2.0]$ on $L = 1200$). Considering the random distances between neighboring spins, one can find the following MPO tensor encoding both the long-range interaction and randomness:

$$
\begin{align*}
O^{\alpha\beta}_{\alpha\beta} &= 
\begin{bmatrix}
(I_2)^{p_i\prime} & (I_2) & (I_2) & (I_2) \\
(\tilde{\Gamma}_i \otimes S_x)^{p_i\prime} & (I_2) & (I_2) & (I_2) \\
(\tilde{\Gamma}_i \otimes S_y)^{p_i\prime} & (I_2) & (I_2) & (I_2) \\
(\tilde{\Gamma}_i \otimes S_z)^{p_i\prime} & (I_2) & (I_2) & (I_2) \\
B(S_z)^{p_i\prime} & (\tilde{X}^T \otimes S_x)^{p_i\prime} & (\tilde{X}^T \otimes S_y)^{p_i\prime} & (\tilde{X}^T \otimes S_z)^{p_i\prime}
\end{bmatrix}
\end{align*}
$$

where $T$ denotes the transpose, $\tilde{\Gamma}_i = [\lambda_1, \lambda_2, \cdots, \lambda_m]^T$ and $\Gamma_i$ is a diagonal matrix with diagonal elements

$$
\tilde{\Gamma}_i = [\eta_1, \eta_2, \cdots, \eta_m]^T,
$$

and $r_i = |r_{i+1} - r_i|$. Performing DMRG with MPO tensor in Eq. (61), one can find the ground state of Eq. (55) for a given $\alpha$, $\xi$ and random sample.

### B. Results

Now, let us discuss the results obtained that way with DMRG for a chain with open boundary condition and filling factor $N/L = 1/10$.

**Concurrence** First, let us begin with the concurrence results presented in Fig. 18. The left panel shows the averaged concurrence as a function of the index distance $|n-m|$ between two spins at sites $m$ and $n$. The distribution of concurrence at a given index dist-

FIG. 15. Average block entanglement entropy as obtained by numerical exact diagonalization for the long ranged XX-chain with a filling factor $N/L = 0.1$ for sizes $L = 140, 160, 180, 200$, for two values of (a) $\alpha = 0.6$ and (b) $\alpha = 2.0$ as a function of the partition length $l$ (physical distance). The average was evaluated over $M = 2000$ realizations for each $\alpha$. The yellow line corresponds to the Cardy law Eq. (48) with a central charge $\tilde{c} = 1.4 \ln(2)$, $b = 1$ and $k' = 0.13$. 

where $T$ denotes the transpose, $\tilde{\Gamma}_i = [\lambda_1, \lambda_2, \cdots, \lambda_m]^T$ and $\Gamma_i$ is a diagonal matrix with diagonal elements

$$
\tilde{\Gamma}_i = [\eta_1, \eta_2, \cdots, \eta_m]^T,
$$

and $r_i = |r_{i+1} - r_i|$. Performing DMRG with MPO tensor in Eq. (61), one can find the ground state of Eq. (55) for a given $\alpha$, $\xi$ and random sample.
FIG. 16. Same as Fig. 15 (b) plotted only for $1 < l < L/4$. The black line is the critical entanglement entropy Eq. (47), corresponding to the Cardy law Eq. (48) for $l \ll L$ with a central charge $\tilde{c} = 1$, $b = 1$, the yellow line is Eq. (47) with $\tilde{c} = \ln 2$.

FIG. 17. Distributions of the entanglement entropy for (a) $\alpha = 0.1$, (b) $\alpha = 0.8$ and (c) $\alpha = 2.8$, where 500 random samples and the system size $N = 22$ are used, and $S_{N0}^0 = \log 2$.

The averaged concurrence $\bar{C}(n)$ shows for some range a power law decay, followed by an exponential decay at larger distance $l$. We observe onset of the exponential decay at smaller lengths $l$ for larger $\alpha$. Near $\alpha = 1$ we find only a power law decay. This is consistent with the appearance of a delocalized critical state. We extract the power of the concurrence function at $\alpha = 1$ and obtain $\gamma = 1.56$, i.e. $\langle C_n \rangle \sim n^{-1.56}$, which is different from the result obtained at the IRFP where $\langle C_n \rangle \sim n^{-2}$, as reviewed above. Note that the horizontal axis of distribution on the right panel is on a log-scale. As expected, the concurrence is widely distributed. It follows a log-normal distribution, its center is shifted by changing $\alpha$, and its width decreases with decreasing $\alpha$.

Entanglement entropy. Let us next consider the entanglement entropy Eq. (46), which one can obtain directly with DMRG from the entanglement spectrum. In Fig. 19, an exemplary result is presented. We see a distinct structure of entanglement of the ground states for a given random sample at $\alpha = 0.8$ and 2. Here, the horizontal axis $n$ stands for the length of the subsystem. At $\alpha = 2$, the entanglement entropy alternates between 0 and $S_{N0}^0 (= \log 2)$ throughout the entire lattice, which indicates that the ground state is to a good approximation a random singlet state, a product of local singlets, whose length is narrowly distributed and thus localized, as expected for the SDFP RS state. On the other hand, at $\alpha = 0.8$, the $S_N$ is non-zero everywhere. It implies that the ground state has a finite degree of entanglement throughout the system. This is consistent with a delocalization transition at $\alpha = \alpha_c$. The averaged entangle-
ment entropy \( [\langle S_{V_N} \rangle_{\text{ens}}] \) over 1000 random samples with \( N = 80 \) is presented in Fig. 20 (a) as a function of the subsystem size \( n \). Here, \( \langle \cdots \rangle_{\text{ens}} \) denotes the ensemble average. The red and black solid lines are fitting curves to Eqs. (51) and (48), respectively. (b) Finite size scaling of \( \alpha_t \) is shown in Fig. 20, we find the critical exponent to be \( \alpha_c = 1.0097 \) in the thermodynamic limit \( 1/N \rightarrow 0 \). This in very good agreement with the SDRG result in Ref. 12, where \( \alpha_c \) is estimated to be \( 1.066 \pm 0.002 \).

Fig. 21 presents the distribution of the entanglement entropy obtained from \( M = 1000 \) random samples. There are peaks at integer multiples of \( S_{V_N}^0 = \log 2 \), both with (red lines) and without magnetic field (black lines). Note that the effect of the magnetic field on the GS depends strongly on \( \alpha \). The distributions of EE are hard to detect any increase with \( \alpha \) see Fig. 21 (c)]. Thus, the DMRG shows that the entanglement entropy decreases as \( \alpha \) is increased beyond the critical value \( \alpha \approx 1 \) and approaches a constant value independent of the subsystem size, as expected in the noncritical regime.

While we cannot extend the DMRG to sufficiently large \( \alpha \) to detect any increase with \( \alpha \), we can check if we can see the increase of the entanglement entropy when the interaction is cutoff exponentially, and the IRFP with critical entanglement entropy is recovered. In Fig. 22 the averaged entanglement entropy as a function of the correlation length is shown as obtained with DMRG. Indeed, while initially a decrease with decreasing correlation length \( \xi \) is observed at a \( \xi \) of the order of twice the
lattice spacing, we observe an increase of the EE again, in agreement with the approach to the IRFP.

**Susceptibility.** Let us consider next the magnetic susceptibility of the ground state under a weak magnetic field $B$. $\langle \chi(\alpha) \rangle_{\text{ens}} = \langle \Delta M(\alpha)/\Delta B \rangle_{\text{ens}}$, where $M = (1/N) \sum_{i=1}^{N} \langle S_i^z \rangle$. Figure 23 (a) shows the result for that susceptibility as function of the system size $N$. Note that it converges to a single curve as increasing the system size, and $N = 80$ is large enough to see the thermodynamic limit. The susceptibility shows a very sharp increase in $0.98 < \alpha < 1.0$ and then increases monotonously with $\alpha$. We believe that the emergence of free spins leads to the significant increase of $\chi$. We also investigate the field dependence of susceptibility with fixed $N = 80$, and results are shown in Fig. 23 (b) and (c). These results strongly suggest $\alpha^*$ to be close to 1 which is consistent with the result obtained above from the concurrence and the result obtained by SDRG in Ref. 12.

### VIII. COMPARISON BETWEEN EXACT DIAGONALIZATION AND DMRG

We have seen in the previous section that the tensor network extension of the DMRG yields results for entanglement measures which are, at least for $\alpha > 1$ not in good agreement with the results obtained with the strong disorder renormalization group method nor the exact diagonalization (ED) presented above. Therefore, let us compare the DMRG results for the ground state properties directly with the ED results. In order to compare with ED, we consider a small chain with $N = 12$ spins, distributed randomly in a chain of length $L = 120$. We have used ED and DMRG to calculate the ground-state wave function, entanglement entropy, and spin-spin correlations among all pairs. Results are illustrated in Fig. 24 for open boundary condition. Calculations with matrix product state (MPS) optimization have been performed using the ITensor C++ library. We run enough sweeps for the entropy to converge to at least $10^{-10}$, and a large number of states, up to 1000, was kept so that the truncation error is less than $10^{-12}$. Regarding the implementation of long-range interaction, as the system is small, we used the AutoMPO method available in ITensor and input all of the terms connecting sites $i$ and $j$, so here we did not consider further approximation like fitting interactions to a sum of exponentials as done in the previous section or more recent SVD compression approaches. The ED results were obtained with the standard ARPACK diagonalization routine as implemented in SciPy.

For small power exponent $\alpha = 1$ both methods are in agreement for all random realizations, both in the entanglement entropy and the spin-spin correlations measurement, as seen in Fig. 24 where each row corresponds to a specific sample. When increasing $\alpha$, however, one can see that the results of DMRG gradually deviate from ED. Particularly, focusing on the entanglement entropy, it is clear that DMRG converges to a state with lower entanglement. As seen from the amplitudes of the many body wave function in the lower Fig. 24 (black) this
is accompanied by a breaking of the particle-hole symmetry. In fact, it is well known that the matrix product state Ansatz of DMRG tends to prefer states of lower entanglement, when states are close in energy. Indeed, although the states obtained with ED shown in the lower Fig. 24 (yellow) are found to have the same energy, the ED ground state is particle-hole symmetric and more strongly entangled. Thus, this is evidence that the DMRG omits some of the singlets formed at long distances, which therefore tends to underestimate the entanglement while changing the energy only by an amount smaller than the numerical accuracy. It has been reported that extensions of tree tensor networks (TTN) can capture entanglement properties in disordered systems better\textsuperscript{37}.

IX. CONCLUSIONS

We find that the strong disorder fixed point, characterized by a fixed point distribution of the couplings with a finite dynamical exponent, describes disordered quantum systems of long-range coupled antiferromagnetic spin chains consistently. However, the lowest-order SDRG, with its RS state, is found not to be sufficient to obtain the typical value of the concurrence. We therefore proposed and implemented a correction scheme to the RS state, allowing us to obtain the leading order corrections. These corrections yield a power law distance scaling of the typical value of the concurrence, which we demonstrate both by a numerical implementation of these corrections and by an analytical derivation. They are found to be in agreement with each other.

The entanglement entropy (EE) is calculated using SDRG numerically and analytically and found to be logarithmically enhanced for all $\alpha$, whereas the effective charge is found not to depend on $\alpha$ and to be $c = \ln 2$, in agreement with an analytical derivation. However, the analytical derivation uses assumptions on the correlation between singlets, and in a first attempt to include these correlations, we arrived at a smaller central charge. Therefore, a more rigorous derivation is called for, which we leave for future research.

While we confirm with numerical exact diagonalization (ED) the logarithmic enhancement of EE and a weak dependence on $\alpha$, it fits in a wide range of distances $l$ a critical behavior with a central charge close to $c = 1$, reminiscent of the clean Haldane-Shastry model with power law decaying interaction with $\alpha = 2$. Indeed, also the concurrence, derived with numerical ED is found to decay with a power law, whose exponent is smaller than the one found by SDRG, $\gamma = 2$ and closer to the one known for the Haldane-Shastry model, $\gamma = 1^{15,38}$. However, at small distances $l \ll L$ we find strong deviations, which may indicate that the central charge converges to the SDRG value $c = \ln 2 < 1$ for large sizes. Therefore in future research the exact diagonalization should be extended to larger systems to check for which ranges of $\alpha$ disorder is relevant so that the system converges to the SDRG fixed point.

We also present results obtained with DMRG and find agreement with ED for sufficiently small $\alpha < 2$, while for larger $\alpha$ DMRG is found to tend to underestimate the entanglement entropy and finds a faster decaying concurrence. As it is known from previous studies that DMRG underestimates Entanglement, extensions like the tree tensor network have been suggested, which also might allow to study larger system sizes. We note that it has been previously suggested that a delocalization occur at a critical value of $\alpha_c$.\textsuperscript{11} As we find a logarithmic length dependence for all $\alpha$, as expected at a critical point, we cannot discern the delocalization transition at a specific $\alpha_c$ in the entanglement properties within this approach.

FIG. 24. Comparison between ED and DMRG for $N = 12$ spins distributed randomly over length $L = 120$ with open boundary condition: From the $M = 1000$ realizations, we show the entanglement entropy, the spin-spin correlation, and the ground-state wave function of three samples. In the lower figure the vertical red-line is plotted at the particle-hole point, as a guide to the eyes.
Appendix A: Solution of the Master Equation at the Fixed Point

In this appendix we show how to derive the solution of the master equation at the fixed point. We denote \( \mu = \frac{1}{\Gamma(\Omega)} \).

First, we multiply by \( \int z^i dJ \) the two sides of Eq. (7), and then plug in the Ansatz for \( P(J, \Omega) \), Eq. (9),

\[
\int_0^\Omega dJ z^i \Omega^\mu J^{\mu-1}(\mu^2(\Omega) - \Omega \mu^2 \mu - \Omega \mu' \ln \left( \frac{J}{\Omega} \right))
\]

\[
= \mu^6 \Omega^{-5\mu-1} \int_0^\Omega dJ_1 J_1^\mu \int_0^\Omega dJ_3 dJ_4 (J_3 J_4)^{\mu-1}
\times \left[ \int_0^\Omega dJ_1 J_1^{\mu-1} J_1^{(J_4 - J_3)} \int_0^\Omega dJ_2 J_2^{\mu-1} J_2^{(J_3 - J_4)} \right]
\]

The left hand side of Eq. (A1) can be integrated and expressed in terms of hypergeometric functions. One can also integrate over \( J_3, J_1, J_2 \) on the L.H.S., yielding

\[
M(\mu, \mu + 1, \Omega \ln(z)) \left( \frac{\mu}{\Omega} - \frac{\mu'}{\mu} \right)
+ \mu^2 \int \left[ (J_4 - J_3)^{-2\mu} \gamma(\mu, J_3 - J_4) \ln(z) \gamma(\mu, J_4 - J_3) \ln(z) \right]/(A2)
\]

Here \( \gamma, 2F2 \) and \( M \), are respectively the lower incomplete gamma function, the generalized hypergeometric function, and the confluent hypergeometric function, defined by

\[
\gamma(s, x) = \int_0^x t^{s-1} e^{-t} dt
\]

\[
M(\mu, \mu + 1, x) = \sum_{n=0}^{\infty} \frac{\mu^2 x^n}{n!(\mu + n)}
\]

\[
2F2(\mu, \mu + 1, \mu + 1, \mu + 1, \Omega \ln(z)) = \sum_{n=0}^{\infty} \frac{\mu^2 x^n}{n!(\mu + n)^2}
\]

Using the identity \( \gamma(a, -z) = -(a^n/a) M(a, a + 1, z) \) and Eqs. (A3) one can rewrite Eq. (A1) as

\[
M(\mu, \mu + 1, \Omega \ln(z)) \left( \frac{\mu}{\Omega} - \frac{\mu'}{\mu} \right)
+ \mu^2 \int \left[ (J_4 - J_3)^{-2\mu} \gamma(\mu, J_3 - J_4) \ln(z) \gamma(\mu, J_4 - J_3) \ln(z) \right]/(A2)
\]

Finally, we evaluate the last double integral,

\[
\int_0^\Omega \int_0^\Omega dJ_3 dJ_4 (J_3 J_4)^{\mu-1} (J_4 - J_3)^{2k} = \frac{\Omega^{2\mu} \Omega^{2k}}{k + \mu} \frac{\Gamma(\mu) \Gamma(2k + 1)}{\Gamma(\mu + 2k + 1)}
\]

Allowing us to get the integrated form of the constraint equation,

\[
M(\mu, \mu + 1, \Omega \ln(z)) \left( \frac{\mu}{\Omega} - \frac{\mu'}{\mu} \right) + \mu^2 F_2(\mu, \mu + 1, \mu + 1, \Omega \ln(z))
\]

\[
= \frac{\mu^6}{\Omega} M(\mu, \mu + 1, \Omega \ln(z)) \sum_{k=0}^{\infty} \frac{\Gamma^2(\mu) \Gamma(2k + 1) (\Omega \ln(z))^{2k}}{(k + \mu) \Gamma^2(\mu + 2k + 1)}
\]

Which can be rewritten using Eq. (A3) in the form

\[
-\mu' (\Omega \sum_{n=1}^{\infty} \frac{(\Omega)^n}{(n-1)!}) (\mu + n)^2 = \frac{\mu^6}{\Omega}
\times \sum_{k=1, k'=0}^{\infty} \frac{\Gamma^2(\mu) \Gamma(2k)! (\Omega)^{2k+k'}}{(k + \mu) \Gamma^2(\mu + 2k + 1) k!(\mu + k')}
\]

Here we defined \( t = \ln(z) \).

Appendix B: Benchmark Model Results

1. Haldane-Shastry model

Among the spin models in one dimension, the Haldane-Shastry chain\(^{15}\) is interesting for several reasons. It is an antiferromagnet with \( 1/r^2 \) exchange interactions, and it possesses a Yangian symmetry which makes it integrable, therefore, exactly solvable. This model is defined by

\[
H = J \frac{\pi^2}{N} \sum_{j=1}^{N} S_i S_j \frac{d(z_i, z_j)}{2^2}
\]

where \( d(z_i, z_j) \) is the distance between two arbitrary sites on a ring, as given by

\[
d(z_i, z_j) = |z_i - z_j| = 2 |\sin(\frac{\pi(i - j)}{N})|.
\]

The HS spin chain is known to be critical and indeed connected to the WZW conformal field theories in the long wave length limit. More precisely, the critical theory of the model in Eq. (B1) is the WZW model \( SU(2)_k \) at level \( k = 1 \), with a central charge \( c = 1 \). In this section we show, as a benchmark, the result of our implementation of exact diagonalization for the clean Haldane Shastry model, for \( N = 22 \) spins, recovering the \( c = 1 \) analytical result, as shown in Fig. 25.

2. Random Heisenberg XX-model

In this section, we implement the exact diagonalization procedure for the random short ranged AFM XX-Heisenberg model, defined by its Hamiltonian:

\[
H = \sum_{i=1}^{N-1} J_i \left(S^x_i S^x_{i+1} + S^y_i S^y_{i+1}\right)
\]

Where \( \{J_i\}_{i=1}^{N-1} \) are uncorrelated positive random variables, drawn from a distribution \( P(J) \). In Ref. 9, it was shown with SDRG method that, given an interval of length \( l \) embedded in the infinite line, the average entanglement entropy of this interval, with the rest of the chain scales for large \( l \) as Eq.
with \( c = \bar{c} = 1 \), \( k' = 0.74 \).}

\((48)\) with \( b = 2 \), corresponding to the entanglement entropy of a critical system \(\text{Eq} \ (47)\), with an effective central charge \( \bar{c} = c \times \ln(2) \), where \( c = 1 \) is the central charge of the pure XX-Heisenberg model. Fig. (26) shows ED results for a sample with \( N = 22 \) spins with open boundary conditions for the entanglement entropy averaged over 200 random samples as function of partition size \( n \). A strong even-odd effect is seen. The yellow line is the Cardy law \(\text{Eq} \ (48)\) with \( \bar{c} = 0.8 \ln 2 \), \( b = 1 \) and \( k' = 0.68 \), which is in good agreement with the result obtained for a RS state \(\text{Eq} \ (51)\), when \( c_2 = 0.8 \). The pink line is \(\text{Eq} \ (48)\) with \( \bar{c} = 2 \ln 2 \), \( b = 1 \) and \( k' = 0.37 \).

Fig. (27) shows the result of exact diagonalization for this model, considering a system of \( N = 22 \) spins with periodic boundary conditions. ED reproduces the results obtained analytically in Ref. 9, and derived in this article, \(\text{Eq} \ (51)\) for \( b = 2 \), when \( c_2 = 1 \).

### Appendix C: Entanglement Entropy With Corrections to the Random Singlet State.

Having the RS state with corrections \( |\psi\rangle \), \(\text{Eq} \ (30)\) we can write the density matrix to calculate the entanglement entropy beyond the RSS using directly the definition of the von Neumann entropy \(\text{Eq} \ (46)\). Given that the RS state with corrections \( |\psi\rangle \) is not a product state, there are no simple combinatorical arguments, such as the counting of crossing singlets, since the entropy of a superposition state is not the sum of the individual entropies. Moreover, a closed formula using the definition \(\text{Eq} \ (46)\) is not feasible due to the dependence of the sums on the specific realization of the RSS, which makes taking the partial trace inconceivable without considering every single possible scenario, i.e., there are as many outcomes for the partial trace as there are possible random singlet states on the chain \(\sim N \).

A possible solution to this problem is to start by taking into account in \(\text{Eq} \ (30)\) the term with the largest coefficient in the sum corresponding to the corrections to two singlet states, only. Once this is achieved one possibly can then close the argument recursively to take into account all corrections. Keeping only the largest coefficient in \(\text{Eq} \ (30)\) we get

\[
|\psi\rangle \approx c|\psi_{RS}\rangle + c\delta J(|+_{nl}\rangle|-_{mk}\rangle + |_{nl}\rangle|+_{mk}\rangle)_{(ij)\neq(nl)\neq(mk)}|0_{ij}\rangle, \quad (C1)
\]

where

\[
\delta J = \frac{J_{nm} + J_{lk} - J_{nk} - J_{ml}}{J_{nl} + J_{mk}}, \quad (C2)
\]
is the maximum coefficient appearing in Eq. (30), and the coefficient $c_\psi$ needs to be redefined as

$$c_\psi = \frac{1}{\sqrt{1 + 2\delta J^2}},$$

(C3)
in order to keep the approximated state properly normalized. Now, let us consider a situation, where the RSS state is such that $k$ singlets cross the partition boundary, giving the EE

$$S(k) = k \ln 2.$$  

(C4)

With the corrected state Eq. (C1) we find after a lengthy but straightforward calculation, that it is possible to arrive at a conditional closed form for the entanglement entropy that depends where the two converted singlet pairs \{nl\} and \{mk\} are located, relative to the partition boundary. There are three distinguishing cases that give rise to different expressions for the entanglement entropy as a function of the number of crossing singlets and triplets $k$ (Here we set $c = c_\psi$ in Eq. (C3), which in the limit of no corrections ($\delta J \rightarrow 0, c \rightarrow 1$), simplify to Eq. (C4).

**Case 1:** Each of the two converted singlets \{nl\} and \{mk\} are at opposite sides of the cut and none of them cross the boundary:

$$S(k) = -c^2 \ln \left( \frac{c^2}{2k} \right) - (1 - c^2) \ln \left( \frac{1 - c^2}{2k + 1} \right).$$  

(C5)

**Case 2:** Both converted singlets cross the boundary between subsystems, for $k \geq 2$:

$$S(k) = -\frac{c^2}{2} \ln \left( \frac{c^2}{2k} \right) - \frac{c^2}{4}(2\delta J + 1)^2 \ln \left( \frac{c^2}{2k} (2\delta J + 1)^2 \right)$$

$$- \frac{c^2}{4}(2\delta J - 1)^2 \ln \left( \frac{c^2}{2k} (2\delta J - 1)^2 \right).$$  

(C6)

**Case 3:** Any other relationship between the converted pairs and the boundary, e.g., both pairs are part of the same subsystem or only one of them crosses the boundary. In this case, the approximated state brings no correction to the entropy, giving the same value obtained at the IRFP, Eq. (C4).

Moreover, as seen in Fig. 28(a) for the specific instance $k = 3$, case 1 (Eq. (C5), dashed line) gives a higher entropy than the one at the IRFP (Eq. (C4), continuous line). This is expected since the corrected state is a superposition of states that differ only in spin pairs \{nl\} and \{mk\}, which live on opposite sides of the subsystem boundary, and therefore results in an enhancement of the quantum correlations between subsystems. On the other hand, case 2 (Eq. (C6), dashed-dotted line) gives a lower entropy than that of Eq. (C4), also for all values of $c \neq 1$. Again, this is expected due to the fact that the extra correction terms are destroying the RSS, which in this case is the maximally entangled state, given that both pairs cross the boundary. It is worth noting, that in order to plot the entropy in Eq. (C6), Eq. (C3) was inverted in order to obtain $\delta J(c^2)$, and the positive root was chosen. However, since Eq. (C6) is an even function of $\delta J$, this choice becomes trivial.

We observe that, even though the plot is only shown for the specific case of $k = 3$ crossing singlets, the above statements remain true for all values of $k$, as can be inspected via Eqs. (C5) and (C6).
