ABSTRACT

Introduction Recent evidence suggests an underlying movement disruption may be a core component of autism spectrum disorder (ASD) and a new, accessible early biomarker. Mobile smart technologies such as iPads contain inertial movement and touch screen sensors capable of recording subsecond movement patterns during gameplay. A previous pilot study employed machine learning analysis of motor patterns recorded from children 3–5 years old. It identified those with ASD from age-matched and gender-matched controls with 93% accuracy, presenting an attractive assessment method suitable for use in the home, clinic or classroom.

Methods and analysis This is a phase III prospective, diagnostic classification study designed according to the Standards for Reporting Diagnostic Accuracy Studies guidelines. Three cohorts are investigated: children typically developing (TD); children with a clinical diagnosis of ASD and children with a diagnosis of another neurodevelopmental disorder (OND) that is not ASD. The study will be completed in Glasgow, UK and Gothenburg, Sweden. The recruitment target is 760 children (280 TD, 280 ASD and 200 OND). Children play two games on the iPad then a third party data acquisition and analysis algorithm (Play.Care, Harimata) will classify the data as positively or negatively associated with ASD. The results are blind until data collection is complete, when the algorithm's classification will be compared against medical diagnosis. Furthermore, parents of participants in the ASD and OND groups will complete three questionnaires: Strengths and Difficulties Questionnaire; Early Symptomatic Syndromes Eliciting Neurodevelopmental Clinical Examinations Questionnaire and the Adaptive Behaviour Scales-II. The primary outcome measure is sensitivity and specificity of Play.Care to differentiate ASD children from TD children. Secondary outcomes measures include the accuracy of Play.Care to differentiate ASD children from OND children.

Ethics and dissemination This study was approved by the West of Scotland Research Ethics Service Committee 3 and the University of Strathclyde Ethics Committee. Results will be disseminated in peer-reviewed publications and at international scientific conferences.

Trial registration number NCT03438994; Pre-results.

INTRODUCTION

Autism spectrum disorder (ASD) is a childhood neurodevelopmental disorder with a prevalence estimated as high as 1 in 59 children in the USA.1 In the UK, ca. 700 000 individuals live with autism2 and the aggregate annual cost of healthcare and support is £28 billion.3 Early identification and consequent early therapeutic intervention may afford family and caregivers opportunity to adjust, and can trigger early healthcare intervention and children’s services support. Such provision can produce significant, lifelong health and economic benefit.4–7

Early diagnosis of children with autism remains complex and can be difficult to obtain. Diagnosis currently relies on specialist medical expertise with diagnostic instrument dependent on subjectively rated scores during child observations, parent interviews and testing. These instruments are time
Recent identification of motor disturbance in young children who develop ASD presents a new target for early assessment. ASD is typically considered a social and emotional disorder. Therefore, current diagnostic instruments directly address social and emotional aspects of the syndrome. However, motor control underpins social engagement, emotional expression, linguistic and cognitive development and its precise subsecond form is now accessible to non-invasive, ecologically valid assessment methods from the neonatal stage onward. These methods of motor analysis can detect risk for neurodevelopmental disorder well before current methods allow, but more work is needed to better characterise these motor signatures. In particular, characterisation of an autism-specific motor signature may serve as an accessible, non-invasive biomarker of the disorder for its early identification, but more work is needed to better define its specificity within the broad clinical population.

Children with ASD exhibit a motor signature with a disruption in the development of purposeful movement, evident in, for example, delays in the attainment of motor milestones, poor coordination, unusual gait patterns and difficulties in gross and fine motor skills. In a meta-analysis of all evidence, Fournier et al concluded motor disruption to be a core feature of ASD. This motor perspective is beginning to gain significant scientific agenda. Smart tablet serious games are an especially attractive format, because children with ASD do not readily share the same social intentions as the researcher. On the other hand, children with ASD and typically developing (TD) children alike typically enjoy screen-based games and will engage these freely of their own volition, presenting an attractive and ecologically valid paradigm for assessment.

In previous work, Anzulewicz et al tested a novel, serious smart tablet game for early identification of young children with autism. Two attractive educational cartoon games (Duckie Deck, http://duckiedeck.com) were engineered with bespoke code to collect sensor data (touch screen and triaxial accelerometer and gyroscope) as the children engaged for 5 min with each game. Machine learning analysis identified those children diagnosed with autism with 93% accuracy, proving the principle that smart game identification of ASD in children was a viable solution for assessment. Furthermore, this methodology required no professional training to deploy, no verbal instructions were required to engage the child, and only limited supervision was necessary. The result of the assessment was purely statistical; no subjective coding was required. Thus, we proposed this serious game digital health instrument could serve as an attractive addition to the diagnostician’s tool box, as a paediatric public health screening tool, or for teachers and psychologists in schools.

This game is now developed into a commercial product called Play.Care that is entering its final stages of preparation by Harimata sp.z o.o. (https://harimata.pl/) with support from a European Union Horizon 2020 Small to Medium Enterprise Instrument (grant No. 756079) to maximise its development and availability. This diagnostic study is a part of that grant to test with gold-standard methodology the classification accuracy of the serious game assessment, and therefore its value in educational, clinical and population screening contexts, or as a tool in clinical diagnosis.

A current best performance for a validated subcomponent of the gold standard in autism diagnosis, the Autism Diagnostic Observation Schedule (ADOS) V.2, yields diagnostic performance of, at most, 91% sensitivity and 71% specificity, or 82% sensitivity and 88% specificity when the algorithm is adjusted to increase specificity. In our previous pilot work, the Play.Care iPad serious game assessment demonstrated a sensitivity and specificity of 83% and 85%, respectively. Serious game assessment by smart device appears to be an attractive resource that could improve sensitivity and specificity ratings, while at the same time improving accessibility. Moreover, the device offers a pure statistical computation without the disadvantages of subjectively rated codes.

The aim of this study is to validate the predictive value of the Play.Care for ASD diagnosis by conducting a multisite, controlled diagnostic study. Further aims include assessing the ability of Play.Care to differentiate ASD from other childhood developmental disorders.
Limitations inherent in the earlier pilot study are overcome in this diagnostic trial. The pilot study was based on a sample of 82 children recruited from a small number of specialist day-care centres in Poland. Such limited subject recruitment is prone to selection bias and site-specific effects and precludes assessment of predictive value in population-based settings. Furthermore, the pilot study employed the same dataset to train and test the machine learning algorithm. It did so with 10 repetitions of a 10-fold cross-validation procedure that is not prone to overfitting. Nevertheless, it only trained and tested patterns on that particular dataset. To alleviate both concerns, this study sets out to test an adaptation of the algorithm previously developed and published on new, blinded data obtained independently of the Play.Care software engineers and commercial concerns in an international, multisite diagnostic evaluation with a general population and clinical cohort and with phase III clinical study structure and size. This trial is designed to test the Play.Care assessment to determine its generalised, real-world prediction rates across the range of possible ASD expression, as well as against TD and other neurodevelopmental disorder (OND) variability. Should the sensitivity and specificity of the assessment fall within clinically useful levels comparable to or exceeding current observer-rated tests (ADOS-2, Autism Diagnostic Interview-Revised, ADI-R), we expect this instrument to be an attractive and useful addition to the assessment and diagnostic tool box, accessible to a wide range of professionals in psychiatry, paediatrics and specialist children’s services, and those in education. This solution is attractive and timely, and benefits from a surge in machine learning analysis of smart tech data. In our case, this is a fun, useful and mobile serious game for autism assessment.

**METHODS AND ANALYSIS**

**Study design**

This study is a phase III prospective, diagnostic classification study. The protocol follows the Standards for Reporting Diagnostic Accuracy Studies guidelines. The study is a multicentre, international trial based in Glasgow, Scotland, UK and Gothenburg, Sweden. The Glasgow cohort comprises a clinical sample and the Gothenburg cohort comprises a general population sample. The study has three groups of participants recruited across two sites (table 1): children who have received a clinical diagnosis of ASD; children who have received a clinical diagnosis of an (OND; see table 2 for inclusion/exclusion criteria); and children TD. The recruitment phase of the study runs from 1 January 2018 to 30 June 2019 with data analysis for

| Table 1 | Participant numbers across groups and sites |
|---------|---------------------------------------------|
| **Site** | **ASD** | **OND** | **TD** | **Total** |
| Glasgow | 100 | 140 | 180 | 420 |
| Gothenburg | 180 | 60 | 100 | 340 |
| **Total** | **280** | **200** | **280** | **760** |

ASD, Autism Spectrum Disorder; OND, Other neurodevelopmental disorder; TD, typically developing.

| Table 2 | Participant inclusion and exclusion criteria |
|---------|---------------------------------------------|
| **Group** | **Inclusion criteria** | **Exclusion criteria** |
| All participants | Aged 30 months to 5 years 11 months | Uncorrected sensory (visual, hearing) impairments |
| Participants with a diagnosis of ASD | Diagnosis of autism spectrum disorder on the basis of DSM-5 criteria or equivalent ICD-10 framework | Presence of any motor impairments or behavioural impairment that may obstruct testing |
| Participants with a diagnosis of OND | Other childhood developmental disorders including, but not limited to intellectual disability, non-verbal disability, communication disability, attention deficit hyperactivity disorder and developmental coordination disorder, Down’s syndrome and cerebral palsy. | Subclinical or secondary expressions of ASD |
| TD participants | Within age range | Uncorrected hearing or vision impairments |

ASD, Autism Spectrum Disorder; OND, Other neurodevelopmental disorder; TD, typically developing.
primary and secondary outcome measures concluding and reports submitted by 31 October 2019.

Patient and public involvement
The research questions addressed in this study were the result of previous dialogue between research, digital health, commercialisation and clinical, educational, and parental need. Demand for early, accessible and computationally accurate assessment of ASD was found to be growing within the context of a rise in awareness and incidence of diagnosed autism. Yet, wait-list times remained high and demand on clinician time increased. An accessible instrument was needed that could identify autism and differentiate it from ONDs—the primary and secondary outcome measures of this study—with ease and reduced expert involvement. Patient involvement helped inform recruitment patterns of this diagnostic study, particularly to fit around family care and education patterns, and especially the children’s daily routine. The latter was an important consideration for timing subject engagement. Educators and clinicians assisted with the early stages of pilot protocol development, ensuring the Play.Care test phase would fit alongside the normal day routine in the nursery, school, clinic, or in some cases, in the home.

Participants
A total of 760 children aged 30 months to 5 years 11 months will be recruited. Table 1 illustrates the participant numbers between sites and groups and table 2 details inclusion and exclusion criteria for each group.

Group sizes were decided on by assuming Play.Care will achieve a moderate 85% sensitivity. In this case, a study with 200 children with ASD will yield a confidence interval (CI) with a width of ±4.9%, that is, the final sensitivity calculation will be accurate to within this range. The target recruitment size for this group is 280 children to afford some reduction in sensitivity or a significant non-completion or under-recruitment rate while preserving a narrow CI. The wider population recruited in this study in comparison to the earlier study may reduce sensitivity of the algorithm’s prediction, inclusion of low functioning children with ASD increases the likelihood of disengagement with or disinterest in the Play.Care assessment, and the new recruitment strategies employed in this study may present recruitment challenges. Assuming a similar level of specificity, the same precision will be obtained with 200 TD children. Furthermore, if the sensitivity (or specificity) is as high as 90%, there will be 80% power to show that the sensitivity (or specificity) exceeds 83.0%, and 90% power to show it exceeds 81.9%. On the other hand, if the sensitivity (or specificity) is only 70%, there will be 91% power to show that it is below 80%. That is, if the Play.Care assessment is underperforming, which is the major concern of healthcare services, this study has a high probability of detecting it.

For the Glasgow cohort, recruitment of children with ASD or OND will be facilitated through the National Health Service (NHS) Greater Glasgow and Clyde Specialist Children’s Services, other specialist children’s centres, nurseries and schools. ASD and OND recruitment will occur via two streams. The first will recruit children who receive a positive diagnosis of ASD or OND following an assessment at an NHS clinic. The second will recruit children already diagnosed with ASD or OND from specialist nurseries, preschools and development centres. TD children will be recruited from local private nurseries in the Greater Glasgow area.

The Gothenburg cohort is a general population sample as all children are screened for ASD within the Gothenburg area at 30 months. Families of children screened positively for ASD are referred to the Gillberg Neuropsychiatry Centre (GNC) in Gothenburg for neuropsychiatric assessment and it is at this stage that families will be made aware of the study and asked if they would like to participate. OND children in Gothenburg will be recruited through speech and language therapists in collaboration with the GNC.

Diagnostic device
The diagnostic tool under assessment in this study is the Play.Care iPad mini application, developed by Harimata sp. z o.o., Kraków, Poland. The assessment consists of two serious games played on the iPad. The first is called ‘sharing’ and requires the child to tap a piece of food to split it into four pieces, available for sharing with four cartoon game characters waiting patiently (figure 1A). The second game is called ‘creativity’ and requires the child to trace the outline of a drawing and then colour it in (figure 1B). Each gameplay session consists of a 2 min training phase where the researcher and/or parent can assist the child, and a 5 min assessment phase where the child must play unassisted. Data are collected for analysis only from the 5 min assessment phase. Following completion of the assessment, no further participation is required.
Anzulewicz et al.\textsuperscript{18} details the data analytics employed, including identification of movement patterns by calculation of more than 200 ‘features’ that are assessed by an algorithm developed by machine learning. This algorithm statistically determines whether or not a particular child’s gameplay fits a diagnostic classification. It delivers a statistical prediction.

The gameplay data are collected by two sets of sensors within the iPad (figure 2): (1) the touch screen sensor records the Cartesian coordinate of the touch and its displacement as a gesture travels across the screen with a sampling rate of ca. 60 times per second; and (2) a triaxial accelerometer and gyroscope IMU sensor that detects the small accelerations and rotations of the iPad device with a sampling rate of ca. 100 times per second as the child’s fingers impact on the screen and push into it giving subtle, but significant displaceable forces during a gesture. More than 200 movement ‘features’ are calculated from the raw sensor signals to characterise the child’s gameplay. These include, for example, for the touch screen sensors, the duration of a gesture, its maximum velocity, deviation from a straight line, its peak acceleration and the variance of these parameters across a gameplay session. Features from the raw IMU sensors are similarly extracted by calculating, for example, peak acceleration and rotation for each axis, their means and SDs. These features are described in full in Anzulewicz et al.\textsuperscript{18} Altogether, 10 repetitions of a 10-fold cross-validation procedure were carried out with Regularized Greedy Forest\textsuperscript{42} machine learning enhanced with additional data collected by Harimata in collaboration with the University of Strathclyde prior to this study to produce the algorithm employed in this study. The algorithm is fixed for the duration of the study.

The iPads used in this study are commercially available Apple products currently widely used for leisure, business and research. The iPad specifications employed here are as follows: white or black bevel, silver back iPad mini 4, 128GB. The iOS version will be the latest version available on purchase of the iPads. These specifications will remain fixed for the duration of the study. Furthermore, software updates will be switched off to prevent automatic updates of iOS which may alter the sampling rate of the internal gyroscope and accelerometers.

Figure 2  Movement data acquisition. (A) A child engages freely with the serious game. The tablet is protected by a bumper and placed firmly on a table. Movement data are acquired from (B) the touch screen and (C) the inertial movement unit sensor that detect the kinematics and contact forces of a gesture, respectively. Adapted from Anzulewicz et al. (2016).

Procedure

Potential participants in the ASD and OND assessment stream will first be approached by the clinician undertaking the assessment. The family will be presented with the patient information sheet (PIS) following a positive diagnosis and if the clinician judges them to be suitable participants. The family will complete an interest slip indicating that they are willing to be further contacted by the research team regarding the study. This method was adopted to allow participation to be strictly ‘opt-in’ and to prevent the research team contacting families who had not expressed an interest in participating. After a minimum period of 24 hours, the research team will contact interested families to ask if they would like to participate and to arrange a data collection appointment.

Potential participants in the ASD and OND already diagnosed stream will be first approached at their child’s preschool where the research team will introduce the study during a parent’s evening or similar event. At this point, the PIS will be made available and families who are interested will complete an interest slip, as above, and after a minimum of 24 hours the research team will contact them.

Potential participants who are TD will be recruited through local private nurseries. Nursery staff will circulate the PIS among parents and those who wish their child to participate will return a completed consent form to the nursery. Prior to completing the Play.Care assessment, informed consent will be given by the child’s parents or caregivers. The researcher will then complete a paper-based case report form (CRF) for participants in the ASD and OND groups which details study ID, Scottish Community Health Index (‘CHI’) number, name, address, postal code, phone number and general practitioner details. Participants’ CHI numbers will be recorded to allow follow-up for up to 10 years following participation. This will provide potential future insight into whether diagnoses remain consistent into adolescence and whether any other diagnoses are received. Any further diagnoses can then be compared with the iPad data to determine any correlations between new diagnoses and movement characteristics in childhood.

An additional electronic CRF (eCRF) will be completed detailing the child’s state of arousal and interest on the day of data collection, and for the ASD and OND groups, data from a number of additional psychometric instruments including the Strengths and Difficulties Questionnaire (SDQ), the ESSENCE Questionnaire (ESSENCE-Q) and the Adaptive Behaviour Assessment System (ABAS) at Glasgow and the Vineland Adaptive Behavior Scale in Gothenburg will be recorded. In some cases, additional data will be recorded from instruments employed as part of the child’s neuropsychiatric assessment: Wechsler Preschool and Primary Scale of Intelligence (ADI-R); and ADOS-2. The diagnostic criteria that determine a child’s diagnosis (International Statistical Classification of Diseases and Related Health Problems 10th Revision (ICD-10) or DSM 5) will be recorded.
These psychometric instruments will be completed at an appropriate time during or following the data collection appointment. Additionally, the Glasgow TD group will also carry out the ESSENCE-Q, SDQ and ABAS where possible.

Following completion of the CRF and eCRF, the child will complete the Play.Care assessment. During the assessment, the iPad will be protected within a spongy back cover and bumper (iPad Mini2 Air Protect, Belkin, USA) and will be placed flat on the table top, where it will remain for the duration of the assessment. Parents/caregivers will have the option to consent to their child being videotaped during the assessment. If consent is given, a video camera will be setup and recording will begin prior to the child starting the assessment.

If a participant is unable to complete the assessment (eg, they become distracted or distressed), eCRF and CRF data will still be recorded and the participant will remain a subject in the study. This group will be classified as ‘Play.Care incompletes’ and will provide insight into the clinical applicability of the assessment. This group will be monitored at monthly intervals. If the rate of Play.Care incompletes reaches a level where it will impact the statistical power of the study, administration protocols will be reviewed and adjusted to ensure best possible compliance. This criterion will apply to the Glasgow cohort of participants only. The Gothenburg cohort is a general population sample and therefore participation cannot be controlled dependent on failure rates. If a participant does not have a confirmed clinical diagnosis by the end of the study, they will fall into the category of ‘diagnosis failures’. The acceptable level of diagnosis failures is 7.5%, or, up to 21 subjects in the ASD group and 15 in the OND group.

Throughout the data collection phase, all members of the research team, the trial consortium and Harimata will be blinded to the Play.Care diagnostic prediction until all data have been collected. Following data collection, clinical diagnoses will be compared with Play.Care diagnostic predictions. The primary outcome measure is the ability of Play.Care to identify ASD cases within the general population (Gothenburg) and clinical population (Glasgow) by assessing classification efficacy against TD children. The secondary outcome measures are the ability of Play.Care to differentiate these ASD children from OND children.

**CONCLUSIONS**

This is the first phase 3 equivalent diagnostic study to test the predictive diagnostic accuracy of a smart tablet serious game for the early detection of autism in preschool children. The system is based on computational analysis of motor patterns inherent in the smart tablet sensor gameplay data, with pilot data suggesting sensitivity and specificity comparable or exceeding the current gold standard. This new system offers the benefit of rapid computational analysis with no lengthy subjectively rated clinician-led elements to it, rather the system engages the child’s interest in an attractive tablet-based serious game with raw sensor data analysed by classification algorithm. The instrument’s computational accuracy is tested in this multisite diagnostic study of 760 children.

**DISSEMINATION**

Following completion of data collection, results will be disseminated in the peer-reviewed scientific literature, at national and international scientific conferences, on the Laboratory for Innovation in Autism website (https://www.strath.ac.uk/research/innovationinautism/) and by final report to Harimata sp. z o.o. and the European Commission. A lay summary of the study results will be available for participating families.
