Abstract

To elucidate the influence of shear flow on the generation of magnetic fields through the modification of turbulence property, we consider the case where a large-scale magnetic field is parallel to a large-scale shear flow without direct interaction between the two in the kinematic limit where the magnetic field does not backreact on the velocity. By nonperturbatively incorporating the effect of shear in a helically forced turbulence, we show that turbulence intensity and turbulent transport coefficients (turbulent viscosity, $\alpha$ and $\beta$ effect) are enhanced by a weak shear, while strongly suppressed for strong shear. In particular, $\beta$ is shown to be much more strongly suppressed than $\alpha$ effect. We discuss its important implications for dynamo efficiency, i.e., on the scaling of the dynamo number with differential rotation.

Key words: MHD – stars: magnetic fields – turbulence

1. Introduction

It is now widely accepted that astrophysical and geophysical magnetic fields are not the remains of a fossil field created during the formation of planets or stars (as they would have decayed on a timescale much shorter than their current lifetime), but are self-excited by motions of conductive fluid (for instance, molten iron within the outer liquid core for the Earth and conducting plasma for the Sun). The evolution of a magnetic field $\mathbf{B}$ in a conducting fluid $\mathbf{V}$ is governed by the induction equation,

$$\partial_t \mathbf{B} + \mathbf{V} \cdot \nabla \mathbf{B} = \mathbf{B} \cdot \nabla \mathbf{V} + \eta \nabla^2 \mathbf{B} \quad \text{and} \quad \nabla \cdot \mathbf{B} = 0, \quad (1)$$

where $\eta$ is the ohmic diffusivity. The first term on the right-hand side of Equation (1) is the stretching of magnetic field lines by gradients of the velocity field.

While laminar flows that can generate magnetic fields (dynamo) have been known for a long time, the effect of turbulence on the generation of large-scale coherent magnetic field remains controversial. The main problem is that turbulence tends to create magnetic field at small scales (i.e., scale comparable to the molecular diffusivity $\eta$). Consequently, it inhibits the growth of magnetic field.

Recently, numerical simulations have shown dynamo action on a large scale in nonhelical turbulence in the presence of shear (Yousef et al. 2008). This is an interesting result as the $\alpha$ effect is often thought to vanish in a turbulence without helicity. Various mechanisms have been invoked to explain this large-scale dynamo: stochastic $\alpha$ effect (Proctor 2007), shear amplification of small-scale dynamo (Blackman 1998, 2001) or negative diffusivity (Urpin 2002). Another possibility is the shear-current effect (Rogachevskii & Kleerom 2003) which appears in a turbulent flow with a mean shear flow. In that case, the expression of the $\beta$ coefficient can be rewritten $\beta_{ijk} = -\beta^T \epsilon_{ijk} + F_{ijk} (\nabla \mathbf{U})_0$, where $\beta^T$ is the turbulent magnetic diffusion, while the second term proportional to shear $\nabla \mathbf{U}_0$ acts as a source of magnetic field (Rogachevskii & Kleerom 2003). It is thus of prime importance to investigate how the electromotive force (and consequently the $\alpha$ and $\beta$ coefficients) depends on a large-scale shear flow (Rogachevskii & Kleerom 2003, 2004; Rädler & Stepanov 2006; Brandenburg et al. 2008). In all these previous studies, strong shear is conductive to dynamo as it creates magnetic energy via the $\Omega$ effect, acts as a source of magnetic field (e.g., via the shear-current effect), causes instability (Tobias & Hughes 2004), etc.

One interesting problem, which has not been investigated by most previous authors, is the effect of a stable shear
flow on turbulent transport through the modification of the properties of turbulence alone, without direct influence on $\langle B \rangle$ (i.e., no $\Omega$ effect, shear-current effect). A strong shear flow, without altering $\langle B \rangle$ directly, can reduce turbulent transport as turbulence becomes weak by shear stabilization (Burrell 1997). This is basically because shear advects turbulent eddies differentially, elongating and distorting their shapes, thereby rapidly generating small scales which are ultimately disrupted by molecular dissipation on small scales (see Figure 1). As a result, turbulence level as well as turbulent transport of various quantities can be significantly reduced compared to the case without shear (Kim 2005, 2006; Leprovost & Kim 2006). In particular, in the case when a stable shear flow is parallel to the magnetic field, a dramatic quenching of turbulent magnetic diffusion ($\beta$ effect) was clearly shown in a recent numerical simulation of two-dimensional MHD turbulence (Newton & Kim 2008). In three-dimensional MHD turbulence, by considering a stable shear flow parallel to a uniform large-scale magnetic field, Leprovost & Kim (2008) theoretically predicted that the $\alpha$ effect is quenched by shear as well as magnetic field. In particular, in the kinematic case (for weak magnetic field), the $\alpha$ effect was shown to be reduced as flow shear $A$ increases with the scaling $A^{-5/3}$. However, to understand fully the effect of shear on the dynamo process, it remains to compute its effect on the turbulence diffusion of magnetic field, i.e., the $\beta$ effect, by considering a nonuniform magnetic field. This is what we do in the remainder of this Letter.

In the kinematic limit, the backreaction of the magnetic field on the velocity is neglected. From the physical point of view, this amounts to considering a very weak magnetic field and ignoring the Lorentz Force on the fluid which is quadratic in the magnetic field. For an incompressible conducting fluid, the resulting equations of motion are

$$
\partial_t V + V \cdot \nabla V = -\nabla p + \nu \Delta V + f,
\partial_t B + V \cdot \nabla B = B \cdot \nabla V + \eta \Delta B,
\n \partial_t \nabla \cdot V = \nabla \cdot B = 0.
$$

Here, $B$ is the Alfvén speed, $p$ is the total (hydrodynamical + magnetic) pressure, and $f$ is a small-scale forcing. To study the effect of shear flows and magnetic fields on small-scale turbulence, we prescribe a large-scale flow of the form $U_0 = -x A e_x$ and a sheared large-scale magnetic field $B_0 = (B_0 - \Delta x e_x) e_z$. $B_0$ has been chosen parallel to $U_0$ so that there is no direct interaction between the two fields, e.g., excluding the $\Omega$ effect in our study (in contrast with the case considered by Yousef et al. 2008; Schekochihin et al. 2008, etc.). To solve the equations for the fluctuating velocity field, $u = V - U_0$, and magnetic field, $b = B - B_0$, we use the quasi-linear approximation assuming that the interaction between fluctuating fields is negligible compared to the interaction between large and small-scale fields. The equations for the fluctuating fields can then be written as

$$
\partial_t u + u \cdot \nabla U_0 = -\nabla p + \nu \Delta u + f,
\partial_t b + u \cdot \nabla B_0 + U_0 \cdot \nabla b = b \cdot \nabla U_0 + B_0 \cdot \nabla u + \eta \Delta b,
$$

$$
\n \partial_t \nabla \cdot u = \nabla \cdot b = 0.
$$

In the following, we shall assume a unit magnetic Prandtl number ($\nu = \eta$) and introduce a time-dependent Fourier transform (Kim 2005):

$$
Y(x, t) = \frac{1}{(2\pi)^3} \int d^3 k e^{i(k_x x + k_y y + k_z z)} \tilde{Y}(k, t).
$$

Transforming the time variable from $t$ to $\tau = k_x t / k_y$, Equation (5) can be written as

$$
\partial_{\tau} \tilde{V}_i - \tilde{V}_i \partial_{\tau} \tilde{\delta}_2 = -ik_y \partial_{\tau} \tilde{\delta}_2 - \tilde{\xi} (g^2 + \tau^2) \tilde{V}_i + \tilde{f}_i,
$$

$$
\partial_{\tau} \tilde{B}_i - \tilde{B}_i \partial_{\tau} \tilde{\delta}_2 = -\tilde{B}_i \partial_{\tau} \tilde{\delta}_2 + \tilde{\beta} \tilde{\delta}_2 + i \gamma \tilde{V}_i - \tilde{\xi} (g^2 + \tau^2) \tilde{b}_i,
$$

$$
\tilde{\tau} \tilde{V}_i + \tilde{V}_i + \tilde{\beta} \tilde{V}_i = \tau \tilde{b}_x + \tilde{b}_y + \beta \tilde{b}_z = 0.
$$

Here, $\tilde{R} = B/A$ and $\gamma = B_0 k_y / A$ are the ratio of the magnetic shear and constant magnetic field to the velocity shear, respectively; $\tilde{\beta} = k_x / k_y$ and $\tilde{g}^2 = 1 + \tilde{\beta}^2$; $\tilde{\xi} = \nu k_y^2 / A$ and $\tilde{\gamma} = (\tau, 1, \beta)$. Note that since the first equation of Equation (6) does not involve the magnetic field, the solution to $\tilde{v}_i$ is the same as in the hydrodynamical case (Kim 2005). Using the velocity from Kim (2005), the magnetic fluctuations can be obtained from the second equation of Equation (6) as

$$
\tilde{b}_x = \int_{t_0}^{\tau(t)} dt \frac{f_x(t)(g^2 + \tau^2)}{A} e^{G(t, \tau)} \times \left[ \frac{\tilde{R} \nu}{g^2 + \tau^2} + i \gamma \{Q(\tau) - Q(t)\} - \tilde{R} \tilde{\xi} (\tau - t) \right],
$$

$$
\tilde{b}_z = \int_{t_0}^{\tau(t)} dt \frac{f_z(t)(g^2 + \tau^2)}{A} e^{G(t, \tau)} \left[ \tilde{R} \{1 - \tilde{\xi} \{Q(\tau) - Q(t)\} + i \gamma (\tau - t)\} - \tilde{\beta} \tilde{J}_2 \right] + i \gamma \tilde{J}_1.
$$

Here,

$$
G(t, \tau) = -\tilde{\xi} \{Q(\tau) - Q(t)\}, \quad Q(x) = g^2 x + x^3 / 3,
$$

$$
I(t, \tau) = \frac{1}{2g^2} \tau \int_{g^2 + \tau^2}^{g^2 + \tau^2 + T(\tau) - T(t)} \frac{dx}{x} + T(\tau) - T(t),
$$

$$
J_1 = \int_{t_0}^{\tau} I(t, x) dx, \quad J_2 = \int_{t_0}^{\tau} I(t, x)(g^2 + x^2) dx,
$$

where $T(x) = \arctan(x/g) / g$. $\tilde{b}_s$ can be obtained using incompressibility: $\tilde{b}_y = -\tau \tilde{b}_x - \tilde{b}_z$.

Our main interest is in the total stress and the electromotive force, which determine the growth/decay of the large-scale...
velocity field and the large-scale magnetic field, respectively. First, the stress is $\tau = \langle u_x u_y \rangle - \langle b_x b_y \rangle$. This total stress consisting of Reynolds stress $\langle u_x u_y \rangle$ and Maxwell stress $\langle b_x b_y \rangle$ gives a turbulent viscosity $\nu_T$ in Navier–Stokes equation for large-scale flows, which enhances the molecular viscosity to $\nu + \nu_T$. For the assumed shear flow $U_0 = -Ax$, the turbulent viscosity is given by $\tau = v^TA$. Second, for the magnetic field considered here, the electromotive force reduces to

$$E_y = \langle u_x b_x - u_y b_y \rangle = \alpha_{yx} B_0,$$

$$E_z = \langle u_x b_y - u_y b_x \rangle = \alpha_{zx} B_0 - \beta B.$$ 

Note here that only three coefficients $\alpha_{yx}, \alpha_{zx},$ and $\beta$ are nonvanishing in our configuration. In particular, phenomena such as the $\Omega \times J$ (Rädler & Stepanov 2006) and shear-current effects (Rogachevskii & Kleoerin 2003), which have been advocated to generate magnetic field for nonhelical turbulence subject to rotation and shear as noted previously, are absent here (in contrast with the simulations of Yousef et al. 2008). Note that a shear-current effect could be studied by using a similar analysis but assuming the large-scale magnetic field to depend on $z$ rather than $x$, which will be addressed in a future contribution.

To calculate the correlation functions involved in the transport coefficients, we consider an incompressible forcing which is spatially homogeneous and temporally short correlated with the correlation time $\tau_f$. Specifically, in Fourier space, the correlation function of the forcing is taken as

$$\langle \tilde{f}_l(k_1, t_1) \tilde{f}_j(k_2, t_2) \rangle = \tau_f (2\pi)^3 \delta(k_1 + k_2) \delta(t_1 - t_2) \phi_{lj}(k_2),$$

where the tilde denotes a Fourier transform with respect to the spatial variable. As noted previously, the $\alpha$ effect can be linked to the helicity of the turbulent flow. Consequently, we consider a forcing with both a symmetric part (with energy spectrum $E$) and a helical part (with helicity spectrum $H$) given by

$$\phi_{lm}(k) = E(k) \left( \delta_{lm} - \frac{k_l k_m}{k^2} \right) + i \epsilon_{lmk} k_p H(k).$$

In the following, the turbulence intensity, turbulent viscosity and $\alpha$ effect are expressed in terms of their values in the absence of shear or magnetic field, $e_0, v_0, \alpha_0,$ and $\beta_0$, which can be shown to be

$$e_0 = \frac{\tau_f}{(2\pi)^2} \int_0^{+\infty} dk \frac{E(k)}{v},$$

$$v_0 = \frac{\tau_f}{(2\pi)^2} \int_0^{+\infty} dk k^2 \frac{E(k)}{5v^2k^2},$$

$$\alpha_0 = -\frac{\tau_f}{(2\pi)^2} \int_0^{+\infty} dk \frac{H(k)}{6v^2},$$

$$\beta_0 = \frac{\tau_f}{(2\pi)^2} \int_0^{+\infty} dk k^2 \frac{E(k)}{6v^2k^2}.$$ 

Using equations for velocity in Kim (2005) and Equation (7) and after a long algebra following Kim (2005), we can find the turbulent intensity, stress, and the electromotive force. Omitting the details, here we provide the results only for the limiting case of a weak $(\xi = v k_f^2/A \ll 1)$ and strong shear $(\xi = v k_f^2/A \gg 1)$.

First, in the case where the shear is weak compared to the diffusion rate $(\xi \gg 1)$, we obtain

$$\langle u_x^2 \rangle \sim \frac{2e_0}{3} \left[ 1 + \frac{9\xi^{-2}}{35} \right],$$

$$\langle u_y^2 \rangle \sim e_0 \left[ 1 + \frac{3\xi^{-2}}{70} \right],$$

$$\langle b_x^2 \rangle \sim \frac{e_0}{3} \left[ R^2 + \frac{\gamma^2 \xi^{-2}}{2} + \frac{36R^2 \xi^{-2}}{35} \right],$$

$$\langle b_y^2 \rangle \sim \frac{e_0}{3} \left[ R^2 + \frac{\gamma^2 \xi^{-2}}{2} + \frac{2526R^2 \xi^{-2}}{715} \right],$$

$$\nu_T \sim v_0 \left[ 1 + \frac{4\xi^{-2}}{21} \right],$$

$$\alpha_{yx} \sim \frac{\alpha_0 \xi^{-1}}{5},$$

$$\alpha_{zx} \sim \frac{\alpha_0 \xi^{-1}}{2},$$

$$\beta \sim -\beta_0 \left[ 1 + \frac{26\xi^{-2}}{35} \right].$$

Note that the turbulent viscosity $\nu_T$ and the $\beta$ effect are proportional only to the energy part of the forcing, while the $\alpha$ effect is proportional only to the nonreflectionally symmetric part of the forcing. This is consistent with the expectation that the $\alpha$ effect is due to helical flow, which results from the helical forcing with helicity spectrum $H$. Equation (3) shows that (in the weak shear limit) all the turbulent coefficients increase with shear above their values without shear. The increase in $\beta$ with shear seems to be in agreement with numerical results shown in Figure 1 of Mitra et al. (2009) obtained in a slightly different configuration of $U_0$ and $B_0$. Equation (3) also shows that $\alpha_{yx} \ll \alpha_{yz}$, i.e., the electromotive force is primarily parallel to the large-scale magnetic field (i.e., in the $y$ direction). Furthermore, without shear ($\xi = 0$), we see that $\alpha_{yx} = 0$ showing that this component of the $\alpha$ effect exists only for nonvanishing shear. This is due to the fact that shear induces an anisotropic turbulence (see, e.g., Leprovost & Kim 2007) which in turn triggers off-diagonal components in the $\alpha$ tensor. Note that a different result was obtained by Kim & Dubrulle (2001) who found in two dimensions that the turbulent diffusivity decreases with shear. This difference comes form the fact that Kim & Dubrulle (2001) considered an anisotropic forcing, physically different from the isotropic forcing considered here.

In the opposite limit of strong shear $(\xi = v k_f^2/A \ll 1)$, turbulence intensity and transport coefficients are obtained as follows:

$$\langle u_x^2 \rangle \sim \xi^3 e_0,$$

$$\langle u_y^2 \rangle \sim \xi^{2/3} e_0,$$

$$\langle b_x^2 \rangle \sim \xi^3 e_0,$$

$$\langle b_y^2 \rangle \sim \xi^{2/3} e_0,$$

$$\nu_T \sim \xi^{2/3} v_0,$$

$$\alpha_{yx} \sim \xi^{4/3} \alpha_0,$$

$$\alpha_{zx} \sim \xi^{2/3} \alpha_0.$$

These results show that in the limit of strong shear (compared to scalings given above), all the turbulent quantities are reduced by shear with scalings given above. Note that the magnetic energy $(b^2)$ is more reduced than kinetic energy $(u^2)$. Furthermore, both the velocity and magnetic field in the direction of the shear are reduced more severely than in the perpendicular direction.
manifsting the anisotropic turbulence induced by shear. It is because flow shear directly influences the component parallel to itself (i.e., the $x$ component in Figure 1) via elongation while only indirectly the other two components (i.e., the $y$ and $z$ components in Figure 1) through enhanced dissipation. The electromotive force shows that the $x$-component of the $\alpha$ effect ($\alpha_{xy}$) is now larger than the $y$ one ($\alpha_{yx}$). This is again because, as the shear increases, the anisotropy in the flow increases enhancing the off-diagonal component $\alpha_{xy}$ strongly. Finally, the turbulent diffusivity $\beta$ is reduced as $\xi^{7/3}$ more severely than the $\alpha$ effect ($\alpha_{xy} \propto \xi^{5/3}$), which has interesting implications for the dependence of the dynamo number (characterizing the efficiency of the dynamo) with differential rotation, as discussed in the following.

To summarize, we found that the $\beta$ effect is reduced as $A^{-7/3}$, with a much stronger dependence on the shear than the $\alpha$ effect ($\alpha_{xy} \propto A^{-5/3}$). This result can have interesting implications for solar dynamo which is often envisioned to take place at the base of the convection zone where the shear is quite strong (the so-called tachocline), e.g., to compensate for the weakness of the interface dynamo (Dikpati et al. 2005). In particular, quenching by shear should be incorporated when assessing the efficiency of the dynamo instability is triggered by direct interaction between the large-scale magnetic field (with both components parallel and perpendicular to the velocity field) and velocity field (i.e., $(\mathbf{B}) \cdot \nabla (\mathbf{U}) \neq 0$). Note that in these works, the shear flow is assumed to be weak compared to the diffusion rate, corresponding to our weak shear limit ($\xi \gg 1$). It would be interesting to study the opposite limit of a strong shear ($\xi \ll 1$).

Finally, we showed that turbulence and transport are enhanced for weak shear while quenched for strong shear. Therefore, there is a critical value of the shear for which the turbulence intensity and transport are maximum. As shown by Newton & Kim (2007), this can be due to resonance between the turbulence and shear flow when the characteristic frequency of turbulence matches the advection by shear flow (i.e., the Doppler-shifted frequency vanishes).
