Abstract
We show a sample of some relevant developments in classical and quantum tomography that have taken place over the last twenty years. We will present a general conceptual framework that provides a simple unifying mathematical picture for them and, as an effective use of it, three subjects have been chosen that offer a wide panorama of the scope of classical and quantum tomography: tomography along lines and submanifolds, coherent state tomography and tomography in the abstract algebraic setting of quantum systems.

Keywords: quantum Tomography, Radon transform, coherent states, C*-algebras

1. Introduction

Almost twenty years ago O V Man’ko and V I Man’ko wrote their first contributions to the foundations of quantum tomography ([Ar96, Mn96, Ma97]). We would like to join this celebration and highlight some of the beautiful mathematical structures in classical and quantum tomography uncovered since then. In order to do that we will first present a general conceptual framework that provides a simple unifying mathematical picture for them and three instances that illustrate well both the widespread scope of its applications and its conceptual unifying strength.

1.1. The scope of tomography

Tomography plays a very important role in modern science because it allows us to determine the structural properties of an object using noninvasive methods, i.e. leaving the object under scrutiny in an undamaged state. Therefore, the technique may be applied in medicine, astrophysics, geophysics, material science, physics and nanophysics.

In each field of application, tomography acquires a different form, using different procedures and techniques so that the unifying ideology behind it is sometimes obscured and not immediately available.

In this paper we would like to show its abstract mathematical aspects and framework. Due to the large and wide applicability of tomography, contributors and researchers are disseminated in a large variety of fields and it is therefore not always possible to attribute with certainty an idea to a well identified scientist. However, it is possible to recognize one pioneer in the field, Johannes Radon, and his paper of 1917 [Ra17].

In mathematical terms, the problem formulated by Radon was the following: by integrating a function \( f \), say of two variables \( x \) and \( y \), that satisfies some regularity conditions, along all possible straight lines of a plane, one obtains a function depending on the lines, let us say \( F(l) \), where \( l \) denotes a line. The problem that Radon solved was to reconstruct the initial function \( f \) out of \( F \).

Of course a few questions related to the previous statements are immediate: is every function of lines, satisfying suitable regularity conditions, obtainable by this process? In the affirmative, is the function \( f \) uniquely determined by \( F \) and what is the procedure to find it?

Some generalisations of the procedure occur immediately, going from the plane to generic manifolds, replacing lines with more general submanifolds. As straight lines may be thought of as solutions of the second order equations of motion for a free particle, replace the free particle motion with a more general one. When lines are replaced by submanifolds, describe the family of appropriate submanifolds as solutions of suitable differential equations. If the plane is identified with...
a phase space of a particle with one degree of freedom, is it possible to extend the procedure to general phase spaces and interpret the original function \( f \) as a distribution probability function for a statistical mechanical system? These questions will be explored in section 2.

By thinking of the plane as an Abelian vector group, one can introduce the Wigner–Weyl formulation of quantum mechanics and consider the plane (phase space) as the carrier space of a quantum mechanical picture in terms of a 'quantizer-dequantizer' description. In this manner the original treatment of the problem devised by Radon is carried over to the quantum situation by considering a composition of the Radon procedure with the Wigner–Weyl map. The presence of Weyl's map allows us to also introduce coherent states and therefore extend the various applications to quantum optics.

When the original function \( f \) is thought of as a Wigner function, then the function on lines \( F \) becomes a probability distribution. Thus the probabilistic aspects of quantum mechanics enter naturally in the 'tomographic picture', therefore many of the questions naturally associated with probabilities also enter this description, most notably entropies and thermodynamical concepts. See, for instance, [B09, B10] for a discussion of these aspects and many others, as well as a proof of the completeness of the tomographic picture of quantum mechanics.

This approach to the tomographic description of quantum mechanical systems will be discussed in section 3 where it will be shown that the coherent-state tomographic point of view provides a unifying description that encompasses various descriptions of states of quantum systems like the Wigner quasi-distribution function [W32], the Husimi–Kano \( K \)-function [H40, K56], and Sudarshan’s \( \phi \)-diagonal coherent-state representation [G63, S63].

1.2. General considerations of the mathematical background of tomography

At this stage, and because of the widespread use of tomographic notions, it is relevant to extract the main structures behind the many uses of it.

In order to accomplish that we will replace the space of functions subject to a tomographic treatment with a (subset of a) generic vector space \( V \). The integration procedure along a line may be considered as a linear functional on \( V \), i.e., an element \( \alpha \) of the dual space \( V^* \). The family of all ‘lines’ identifies a subset in \( V^* \), say \( \mathcal{N} \). Now with any vector \( v \in V \), it is possible to associate a function \( F_v \) on \( \mathcal{N} \) by setting,

\[
F_v(\alpha) = \alpha(v),
\]

The 'reconstruction process' may now be formulated in the following terms Given a function \( F(\alpha) \), is it possible to find a unique vector \( v \in V \) such that \( F = F_v \)? Which functions on \( \mathcal{N} \) are associated with vectors in \( V \)?

When the vector space \( V \) itself is realised as a space of functions on a manifold \( M \), our procedure associates a function \( F \) on \( \mathcal{N}^* \) out of a function \( f \) on \( M \). Thus the Radon transform from a vector space \( V = F(M) \) uses a subspace of linear functionals, immersion of \( \mathcal{N} \) into the dual space of \( F(M) \), so that with any function \( \varphi \in F(M) \), a function \( F_\varphi \in F(\mathcal{N}) \) can be constructed.

The reconstruction procedure amounts to inverting the previous map. It is now clear that \( M \) should be a space with a measure, to be able to define integrals, and the measure should have regularity properties so that it also induces measures on submanifolds of \( M \). The chosen family of submanifolds should have a manifold structure so that we identify \( \mathcal{N} \) and a measure on it.

All the various ingredients should be judiciously chosen so that the direct map from \( F(M) \) to \( F(\mathcal{N}) \) should have an inverse. It may happen, and it does, that both the domain, in \( F(M) \), and the codomain in \( F(\mathcal{N}) \), should be properly restricted to achieve the invertibility of the constructed maps.

In what follows we are going to carefully explain how these domains and codomains are chosen in specific instances of classical and quantum tomography.

As tomography allows us to provide a unified picture of classical and quantum systems, we shall first indulge in some general comments concerning the mathematical description of classical and quantum systems.

1.3. Description of classical and quantum systems and tomography

A formal description of a physical system requires the identification of the following entities:

(i) A space of observables \( \mathcal{A} \);
(ii) A space of states \( \mathcal{S} \);
(iii) A pairing between states and observables which gives a real number, the outcome of a measurement of an observable \( A \) of the system in the state \( \rho \).

To take into account specific aspects of the measuring process, we require that a map \( \mu: \mathcal{A} \times \mathcal{S} \to \text{Bo}(\mathbb{R}) \), where \( \text{Bo}(\mathbb{R}) \) denotes the space of probability measures on the Borelian sets of \( \mathbb{R} \), is given. Then, the probability \( P_{A,\rho}(\Delta) \) that the outcome of measuring \( A \) on the state \( \rho \) will lie in the interval \( \Delta \) is given by the measure of the interval \( \Delta \) with respect to the Borelian measure \( \mu(A, \rho) \). If the measure \( \mu(A, \rho) \) is absolutely continuous with respect to the standard Lebesgue measure \( dx \) on \( \mathbb{R} \), then we will get

\[
P_{A,\rho}(\Delta) = \int_\Delta \mu_{A,\rho}(x) dx,
\]

where \( \mu_{A,\rho}(x) \) is the density determined by the measure \( \mu(A, \rho) \), i.e., the Radon–Nikodym derivative of \( \mu(A, \rho) \) with respect to \( dx \).

As for the evolution of the system, we require that a flow structure is given on \( \mathcal{A} \):

\[
\Phi(t, s): \mathcal{A} \to \mathcal{A},
\]

such that

\[
\Phi(t, t) = 1, \quad \Phi(t, s) \circ \Phi(s, r) = \Phi(t, r).
\]

What we have stated are minimal requirements to have a reasonable description of physical systems.
Often additional structures are imposed on observables, states and evolution, as a consequence of the experiments performed on them. For instance, the space of observables of a quantum algebra can be required to carry the structure of a Jordan algebra. With the help of its derivation algebra and a compatibility condition we can construct a Lie–Jordan algebra and from here a C*-algebra.

Where the previous assumptions are made, states are positive normalized elements in the dual space of \( A \) and they constitute a convex body.

The evolution is required to provide automorphisms of the algebra \( A \). When the flow \( \Phi(t, s) \) depends only on the differences \( t - s \), we get a one-parameter group (or semigroup) of transformations, and from here we derive an infinitesimal generator for the flow that allows us to write the evolution in terms of a differential equation.

In section 4 the tomographic description of quantum states in such an abstract algebraic setting will be discussed. A group representation will be used to obtain the tomographic representation and its relation with other tomographic pictures will be analyzed.

2. Tomography along lines and submanifolds

As discussed in the introduction, the Radon transform as originally formulated solves the following problem: to reconstruct a function of two variables from its integrals over arbitrary lines. The original Radon transform [Ra17] maps functions defined on a two dimensional plane onto functions defined on a two dimensional cylinder. The key feature is that the transform is invertible, i.e. the function can always be fully recovered from its Radon transform. There exist several important generalizations of the Radon transform [Ge66, He73, He80, He84, Mi65]. More recent analyses have focused on affine symplectic transforms [Mn95], on the deep relationship with classical systems and classical dynamics [Ma97, As07], and on the study of marginals along curved submanifolds [As08].

The aim of this work is to review the study of generalizations of the Radon transform to multidimensional phase spaces and to frameworks based on marginals along curves or surfaces described by quadratic equations. There are interesting applications of these generalizations to both classical and quantum systems. For classical systems the Radon transform of probability densities in the phase space of a classical particle can be used to obtain the initial probability densities.

The generalization for quantum systems can be achieved by means of the corresponding tomograms of Wigner functions in the phase space [As12]. Notice that the major advantage of the tomographic approach to quantum systems is that it allows a formulation of quantum systems in terms of pure classical probability distributions in phase space.

In the \( \mathbb{R}^2 \) plane, a line

\[
d = q \cos \theta + p \sin \theta, \quad (q, p) \in \mathbb{R}^2 \tag{2}
\]

is parametrized by the distance of the line to the origin \( d \in \mathbb{R}^+ \) and its angle \( \theta \) with a reference line crossing the origin. Considering the phase \( e^{i\theta} \in S^1 \), the family of lines acquires a cylinder manifold structure \( \mathbb{R}^+ \times S^1 \) (see figure 1). There is an alternative group theoretical description of the manifold of straight lines of \( \mathbb{R} \), which can be used for higher dimensional generalizations. The Euclidean group \( E(2) \) acts transitively on the set of lines in the plane, with a stability group given by the translations \( \mathbb{R} \) along the line and the reflections with respect to it, \( \mathbb{Z}_2 \). Therefore the family of lines is given by \( E(2)/(\mathbb{Z}_2 \times \mathbb{R}) \), which is isomorphic to \( \mathbb{R}^+ \times S^1 \).

It is interesting to observe that depending on which subgroup we use to quotient \( E(2) \), we either obtain the plane \( \mathbb{R}^2 \) or the cylinder \( \mathbb{R}^+ \times S^1 \)

\[
\mathbb{R}^2 = E(2)/O(2), \quad \mathbb{R}^+ \times S^1 = E(2)/(\mathbb{Z}_2 \times \mathbb{R}). \tag{3}
\]

The Radon transform is a map of \( L^1 \) functions of \( \mathbb{R}^2 \) into \( L^1 \) functions on \( \mathbb{R}^+ \times S^1 \) given by

\[
\tilde{f}(d, \theta) = \int_{-\infty}^{+\infty} ds \int_{\mathbb{Z}_2} dr f(s \sin \theta + d \cos \theta, \\
- s \cos \theta + d \sin \theta), \tag{4}
\]

where \( s \) is the parameter along the line given by equation (2).

The inversion formula, as given by Radon [Ra17], amounts to considering first the average value of \( \tilde{F} \) on all lines tangent to the circle of center \( (q, p) \) and radius \( r \)

\[
\tilde{f}(q, p) = \frac{1}{2\pi} \int_{-\pi}^{+\pi} d\theta \tilde{F}(q \cos \theta + p \sin \theta + r, \theta) \tag{5}
\]

and then using the Hilbert transform

\[
f(q, p) = -\frac{1}{\pi} \int_{0}^{\infty} \frac{dr}{r} \tilde{f}(q, p), \tag{6}
\]

to reconstruct the original function.

Later on we will provide an alternative expression for the inverse Radon transform in an affine language that extends easily to more general situations, see equation (30). Now we will discuss how the Radon transform can be generalized to higher dimensional spaces.

\[\text{Figure 1. Tomography on the plane.}\]
2.2. Radon transform on the euclidean space $\mathbb{R}^n$

The manifold of straight lines of $\mathbb{R}^n$ crossing the origin is the real projective space $\mathbb{RP}^{n-1}$. This manifold can also be identified with the space of hyperplanes of dimension $n-1$ crossing the origin, and with the quotient of the $S^{n-1}$ unit sphere by the reflection symmetry $Z_2$,

$$\mathbb{RP}^{n-1} = S^{n-1}/Z_2.$$  \hspace{1cm} (7)

In the $\mathbb{R}^n$ space, any hyperplane of dimension $n-1$

$$d = [\mathbf{n} \cdot \mathbf{x}], \quad \mathbf{x} \in \mathbb{R}^n$$ \hspace{1cm} (8)

is parametrized by its distance to the origin $d \in \mathbb{R}^+$ and a unit normal vector $\mathbf{n} \in S^{n-1}$ of $\mathbb{R}^n$, or what is equivalent to a real number $\pm d = \mathbf{n} \cdot \mathbf{x}$ and a ray of the projective $\mathbb{RP}^{n-1}$. Thus, the family $(n-1)$-hyperplanes of $\mathbb{R}^n$ acquires a manifold structure

$$\mathbb{R}^+ \times S^{n-1} \cong \mathbb{R}/Z_2 \times S^{n-1} \cong \mathbb{R} \times S^{n-1}/Z_2 \equiv \mathbb{R} \times \mathbb{RP}^{n-1},$$ \hspace{1cm} (9)

i.e. the manifold of all $(n-1)$-hyperplanes of $\mathbb{R}^n$ which can be identified with $\mathbb{R} \times \mathbb{RP}^{n-1}$. There is another interesting group theoretical description of this manifold which is useful for the analysis of Radon transforms.The Euclidean group $E(n)$ acts transitively on the set of $(n-1)$-hyperplanes with a stability group given by the Euclidean transformations along the $(n-1)$-hyperplane and the $Z_2$ reflections with respect to it. Therefore, the family of $(n-1)$-hyperplanes is parametrized by its distance to the origin $d \in \mathbb{R}^+$ and a ray of the projective $\mathbb{RP}^{n-1}$. The manifold of hyperplanes of dimension $n$ is parametrized by its distance to the origin $d \in \mathbb{R}^+$ and a ray of the projective $\mathbb{RP}^{n-1}$.

It is interesting to observe that, depending on which subgroup we use to quotient, we either obtain the Euclidean space $\mathbb{R}^n$ or the space of its $(n-1)$-hyperplanes,

$$\mathbb{R}^n = E(n)/O(n), \quad \mathbb{R} \times \mathbb{RP}^{n-1} = E(n)/(Z_2 \times E(n-1)).$$ \hspace{1cm} (11)

The natural generalization of the Radon transform for higher dimensional Euclidean spaces $\mathbb{R}^n$ is a map of $L^1$ functions of $\mathbb{R}^n$ into $L^1$ functions on $\mathbb{R} \times \mathbb{RP}^{n-1}$ given by

$$\hat{f}(\xi) = \int_{x \in \xi} \mathbf{dx} f(x)$$ \hspace{1cm} (12)

where the $(n-1)$-dimensional integral is over the points of $\mathbf{x} \in \mathbb{R}^n$ contained in the $(n-1)$-hyperplane $\xi = (d, \mathbf{n}) \in \mathbb{R}^+ \times S^{n-1}$.

There is a dual Radon map which maps $L^1$ functions of $\mathbb{R} \times \mathbb{RP}^{n-1}$ into $L^1$ functions on $\mathbb{R}^n$ given by

$$\tilde{f}(x) = \int_{\xi \in \xi} \mu(\xi') \hat{f}(\xi')$$ \hspace{1cm} (13)

where the $(n-1)$-dimensional integral is extended to all $(n-1)$-hyperplanes $\xi'$ crossing at the point $x$ with the probability measure induced from the measure of the projective space $\mathbb{RP}^{n-1}$ obtained by projection of the standard homogeneous measure of $S^{n-1}$.

The inverse of the generalized Radon transform can then be given in terms of the dual Radon map. However, the explicit formulas originally given by Radon and John [Jo55, Ra17] are different for the cases of even and odd Euclidean spaces,

$$f(x) = \frac{\Gamma(1/2)}{(4\pi)^{n-1/2} \Gamma(n/2)} \times \begin{cases} \Delta^{n-1/2} \int_0^\infty \frac{dr}{r} (-\partial_r)^\xi \tilde{f}(y), & \text{for } n \text{ even,} \\ \Delta^{n-3/2} \tilde{f}(x), & \text{for } n \text{ odd,} \end{cases}$$ \hspace{1cm} (14)

where $\Delta = -\sum_{i=1}^n \partial_i^2$ and

$$\tilde{f}(x) = \int_{\xi \in \xi'} \mu(\xi') \hat{f}(\mathbf{x} \cdot \mathbf{n} + r, \mathbf{n})$$

$$= \frac{\Gamma(n/2)}{2\pi^{n/2}} \int_{S^{n-1}} \mathbf{dn} \tilde{f}(\mathbf{x} \cdot \mathbf{n} + r, \mathbf{n}).$$ \hspace{1cm} (15)

Both cases can be described in a unified way in terms of pseudo-differential operators by the following formula [Fa10, He73, He80]

$$f(x) = \frac{\Gamma(1/2)}{(4\pi)^{n-1/2} \Gamma(\xi/2)} \Delta^{n-1/2} \tilde{f}(x),$$ \hspace{1cm} (16)

or using an equivalent formulation in terms of Riesz potentials [Lu66]

$$f(x) = \frac{1}{\pi^{n-1/2} \Gamma(n/2)} \int_{\mathbb{R}^n} d\mathbf{y} \frac{1}{\|\mathbf{x} - \mathbf{y}\|^{2n-1}} \tilde{f}(y).$$ \hspace{1cm} (17)

2.3. Radon transform on k-planes of euclidean space $\mathbb{R}^n$

The manifold of hyperplanes of dimension $k$ of $\mathbb{R}^n$ crossing the origin is the real Grassmannian manifold $Gr(k, n)$, which can also be identified with

$$Gr(k, n) = \frac{O(n)}{O(n-k) \times O(k)}.$$ \hspace{1cm} (18)

The family of $k$-planes of $\mathbb{R}^n$ acquires a manifold structure

$$\mathbb{R}^{n-k} \times Gr(k, n) = \frac{E(n)}{E(k) \times E(n-k)}.$$ \hspace{1cm} (19)

The generalized Radon transform is a map of $L^1$ functions of $\mathbb{R}^n$ into $L^1$ functions on $\mathbb{R}^{n-k} \times Gr(k, n)$ given by

$$\hat{f}(\xi) = \int_{x \in \xi} \mathbf{dx} f(x)$$ \hspace{1cm} (20)

where the $k$-dimensional integral is over the points of $\mathbf{x} \in \mathbb{R}^n$ contained in the hyperplane line $\xi \in Gr(k, n)$. 

\hspace{1cm}
There is a dual Radon map which maps L functions of \( \mathbb{R}^{n-k} \times \text{Gr}(k, n) \) into \( L \) functions on \( \mathbb{R}^n \) given by
\[
\hat{f}(x) = \int_{x \in \mathbb{E}} e^{i \langle x, \xi \rangle} f(\xi) \, d\mu(\xi),
\]
where the \( (n-k) \)-dimensional integral is extended to all \( k \)-hyperplanes \( \xi \) crossing at the point \( x \) with the probability measure induced from the measure of the Grassmannian manifold \( \text{Gr}(k, n) \) obtained by projection of the Haar measure of \( O(n) \).

The inverse of the generalized Radon transform can then be given in terms of the dual Radon map [Fa10, He73, He80]
\[
f(x) = \frac{1}{(4\pi)^n} \int_{\mathbb{R}^n} e^{i \langle x, \xi \rangle} f(\xi) \, d\nu(\xi),
\]
or using an equivalent formulation in terms of Riesz potentials [Lu66]
\[
f(x) = \frac{1}{\pi^{n-k}} \frac{\Gamma\left(\frac{n-k}{2}\right)}{\Gamma\left(\frac{n}{2}\right)} \int_{\mathbb{R}^n} e^{i \langle x, \xi \rangle} \frac{1}{\|x-y\|^n} \, d\nu(y),
\]
The \( k \)-planes are geodesic submanifolds of \( \mathbb{R}^n \). The generalization of Radon transforms for complete geodesic manifolds is possible. Let us analyze the simplest cases of hyperbolic spaces \( \mathbb{H}^n \).

2.4. Radon transform in hyperbolic spaces \( \mathbb{H}^n \)

The hyperbolic space \( \mathbb{H}^n \) is a negative constant curvature Riemannian manifold which can be identified with an hyperboloid immersed in an \( n+1 \) Minkowski space-time. This space is geodesically complete. Let us denote by \( \mathcal{X}_{\xi} \) the space of all geodesics which are tangent to a \( k \)-plane \( \xi \) of the tangent space at \( x \). For a given \( k \)-plane \( \xi \subset T_x \mathbb{H}^n \) the corresponding submanifold in \( \mathcal{X}_{\xi} \) is a totally geodesic manifold. Due to the special properties of \( \mathbb{H}^n \), the identification of the space \( \mathcal{X}_{\xi} \) of all totally geodesic submanifolds of the same type \( \mathcal{X}_{\xi} \) containing \( x \) and the Grassmannian \( \text{Gr}(k, n) \) is one-to-one. The group of isometries of \( \mathbb{H}^n \) is the Lorentz group \( O(n, 1) \) and the subgroup of isometries which leave invariant a \( k \)-dimensional geodesic submanifold \( \mathcal{X}_{\xi} \) can be identified with \( O(n-k) \times O(k, 1) \). The space of totally geodesic submanifolds \( \mathcal{X}_{\xi} \) can be identified with
\[
\mathcal{X}_{\xi} = \frac{O(n, 1)}{O(n-k) \times O(k, 1)}.
\]
The generalized Radon transform can be defined as
\[
\hat{f}(\xi) = \int_{x \in \mathcal{X}_{\xi}} f(x) \, d\mu_{\xi}(x),
\]
where the \( k \)-dimensional integral is over the geodesically complete submanifold \( \mathcal{X}_{\xi} \) of \( \mathbb{H}^n \) endowed with the probability measure defined by the Riemannian metric induced by its immersion into \( \mathbb{H}^n \).

In the case of hyperbolic spaces \( \mathbb{H}^n \), the dual map
\[
\hat{f}(\xi) = \int_{x \in \mathcal{X}_{\xi}} e^{i \langle \xi, x \rangle} f(\xi) \, d\mu(\xi),
\]
is defined in terms of the probability measure induced from the Haar measure of \( O(n, 1) \) by means of the identification (24).

In hyperbolic spaces \( \mathbb{H}^n \) the inverse Radon transform is obtained by [He80, He84]
\[
f(x) = \int_{\mathbb{H}^n} e^{i \langle x, \xi \rangle} P_k(\Delta) \hat{f}(\xi) \, d\nu(\xi),
\]
where \( P_k(\Delta) \) denotes the geodesic distance between two points \( x, y \in \mathbb{H}^n \), and
\[
P_k(\Delta) = \left\{ \begin{array}{cl}
\prod_{l=0}^{\left\lfloor \frac{k}{2} \right\rfloor} (k-l-n)(k-2l-1+\Delta) & k > 1 \\
1 & k = 1,
\end{array} \right.
\]
where \( \left\lfloor \frac{k}{2} \right\rfloor \) being the integer part of \( \frac{k}{2} \).

A similar analysis can be applied to spaces with constant positive curvature [He80].

2.5. Affine symplectic tomography on the plane

The generalization of the Radon transform to more general tomographic submanifolds which are not totally geodesic is possible by changing the perspective of the Radon transform and considering it as a special case of a Fourier transform which then allows the use of harmonic analysis.

Let us define the Radon transform in the affine language (we called it a tomographic map) [Ge66, Ra17]
\[
\tilde{f}(\lambda, \mu, \nu) = \langle \delta(\lambda - \mu q - \nu p) \rangle = \int_{\mathbb{R}^2} dq \, dp \, f(q, p) \delta(\lambda - \mu q - \nu p),
\]
where \( \delta \) is the Dirac function and the parameters \( \lambda, \mu, \nu \in \mathbb{R} \).

The main advantage of this affine approach is that the inverse transform acquires a simple form [Ge66]
\[
f(q, p) = \int_{\mathbb{R}^2} \frac{d\lambda}{(2\pi)^2} \frac{d\mu}{2} \frac{d\nu}{2} \tilde{f}(\lambda, \mu, \nu) e^{i(\lambda q - \mu p - \nu \mu)}.
\]

We remark the affine tomographic map is homogeneous
\[
\tilde{f}(s\lambda, s\mu, s\nu) = \frac{1}{|s|^2} \tilde{f}(\lambda, \mu, \nu).
\]
2.6. Tomography by hyperplanes

The above construction can be generalized for higher dimensional spaces in a straightforward way. Let us consider a function \( f(\mathbf{x}) \) on the \( n \)-dimensional space \( \mathbf{x} \in \mathbb{R}^n \). It is possible to reconstruct the function \( f \) from its integrals over arbitrary \( (n-1) \)-dimensional hyperplanes.

A generic hyperplane is given by the equation

\[
\lambda - \mathbf{\mu} \cdot \mathbf{x} = 0,
\]

with \( \lambda \in \mathbb{R} \) and \( \mathbf{\mu} \in \mathbb{R}^n \).

We recall that we have seen in section 2.3 that the space of \( (n-1) \)-hyperplanes is diffeomorphic to \( \mathbb{R} \times \mathbb{R}^{n-1} \), which is the set of pairs \( (\lambda, [\mathbf{\mu}] ) \), where \( \lambda \in \mathbb{R} \) is an arbitrary real number and \([\mathbf{\mu}]\) denotes the projective ray of the vector \( \mathbf{\mu} \in \mathbb{R}^n \).

The Radon transform is given by

\[
\mathcal{R}(\lambda, \mathbf{\mu}) = \int_{\mathbb{R}^n} d^n\mathbf{x} f(\mathbf{x}) \delta(\lambda - \mathbf{\mu} \cdot \mathbf{x}),
\]

where \( \delta \) is the Dirac function and the parameters \( \lambda \in \mathbb{R} \) and \( \mathbf{\mu} \in \mathbb{R}^n \). When \( n = 2 \) equation (29) is recovered.

It is very easy to show that the inverse transform of equation (33) reads

\[
f(\mathbf{x}) = \int_{\mathbb{R}^{n+1}} \frac{d\lambda d^n\mathbf{\mu}}{(2\pi)^n} \mathcal{R}(\lambda, \mathbf{\mu}) e^{i(\lambda - \mathbf{\mu} \cdot \mathbf{x})}.
\]

In quantum mechanics this version of affine symplectic Radon transform can be applied to Wigner functions providing a center of mass tomography [Am09]. Moreover, in [Am09] the classical limit for this tomogram was calculated under some additional conditions.

2.7. Tomography with more general submanifolds

A simple mechanism which allows nonlinear generalizations of Radon transforms is the combination of the standard affine transform with a diffeomorphism of the underlying \( \mathbb{R}^n \) space. Let us consider a function \( f(\mathbf{x}) \) on the \( n \)-dimensional space \( \mathbf{x} \in \mathbb{R}^n \). The problem one needs to solve is to reconstruct \( f \) from its integrals over an \( n \)-parameter family of codimension one submanifolds.

We can construct such a family by diffeomorphic deformations of the hyperplanes of \( \mathbb{R}^n \)

\[
\lambda - \mathbf{\mu} \cdot \mathbf{x} = 0,
\]

with \( \lambda \in \mathbb{R} \) and \( \mathbf{\mu} \in \mathbb{R}^n \). Let us consider a diffeomorphism \( \varphi \) of \( \mathbb{R}^n \)

\[
\mathbf{q} \in \mathbb{R}^n \mapsto \mathbf{x} = \varphi(\mathbf{q}) \in \mathbb{R}^n.
\]

The hyperplanes (35) are deformed by means of \( \varphi \) into a family of submanifolds in the \( \mathbf{q} \) space (see figure 2)

\[
\lambda - \mathbf{\mu} \cdot \varphi(\mathbf{q}) = 0.
\]

The Radon transform can be rewritten as

\[
\tilde{f}(\lambda, \mathbf{\mu}) = \langle \delta(\lambda - \mathbf{\mu} \cdot \varphi(\mathbf{q})) \rangle = \int_{\mathbb{R}^n} d^n\mathbf{q} f(\varphi(\mathbf{q})) \delta(\lambda - \mathbf{\mu} \cdot \varphi(\mathbf{q})),
\]

where

\[
J(\mathbf{q}) = \left| \frac{\partial_x}{\partial q_j} \right| = \left| \frac{\partial \varphi_i(\mathbf{q})}{\partial q_j} \right|
\]

is the Jacobian of the transformation and \( f(\mathbf{x}) \) is an arbitrary function.

Now, since

\[
f(\mathbf{x})d^n\mathbf{x} = f(\varphi(\mathbf{q}))J(\mathbf{q})d^n\mathbf{q},
\]

the Radon transform can be rewritten as

\[
\tilde{f}(\lambda, \mathbf{\mu}) = \langle \delta(\lambda - \mathbf{\mu} \cdot \varphi(\mathbf{q})) \rangle = \int_{\mathbb{R}^n} d^n\mathbf{q} f(\varphi(\mathbf{q})) \delta(\lambda - \mathbf{\mu} \cdot \varphi(\mathbf{q})),
\]

with \( \lambda \in \mathbb{R} \) and \( \mathbf{\mu} \in \mathbb{R}^n \).

The inverse transform is given by

\[
f(\mathbf{q}) = \int_{\mathbb{R}^{n+1}} \frac{d\lambda d^n\mathbf{\mu}}{(2\pi)^n} \tilde{f}(\lambda, \mathbf{\mu}) e^{i(\lambda - \mathbf{\mu} \cdot \varphi(\mathbf{q}))},
\]

with a modified kernel

\[
K(\mathbf{q}; \lambda, \mathbf{\mu}) = J(\mathbf{q})e^{i(\lambda - \mathbf{\mu} \cdot \varphi(\mathbf{q}))} = \left| \frac{\partial \varphi_i(\mathbf{q})}{\partial q_j} \right| e^{i(\lambda - \mathbf{\mu} \cdot \varphi(\mathbf{q}))}.
\]

We can now consider different applications of this deformed generalization of the Radon transform.

2.8. Tomography by circles in the plane

The conformal inversion

\[
(x, y) = \varphi(q, p) = \left( \frac{q}{q^2 + p^2}, \frac{p}{q^2 + p^2} \right)
\]

maps the family of lines

\[
\lambda - \mu x - \nu y = 0
\]
into a family of circles
\[ \lambda (q^2 + p^2) - \frac{\mu}{q} - \nu p = 0, \]  
(46)
centered at
\[ \left( \frac{\mu}{2\lambda}, \frac{\nu}{2\lambda} \right) \]  
(47)
and passing through the origin (see figure 3). When \( \lambda = 0 \) they degenerate into lines through the origin.

The Jacobian of the transformation
\[ J(q, p) = \left| \frac{\partial(x, y)}{\partial(q, p)} \right| = \frac{1}{(q^2 + p^2)^2}, \]  
(48)
ever vanishes as a consequence of the fact that \( \varphi \) is an autodiffeomorphism of \( \mathbb{R}^2 \). The origin \( (0, 0) \) is irrelevant for tomographic integral transformations because the singularity only affects a zero measure set.

Equations (41) and (42) then become
\[ \hat{f}(\lambda, \mu, \nu) = \int_{\mathbb{R}^2} dq\, dp \, f(q, p) \delta \left( \lambda - \frac{\mu q}{q^2 + p^2} - \frac{\nu p}{q^2 + p^2} \right), \]
(49)\]and
\[ f(q, p) = \int_{\mathbb{R}^2} d\lambda\, d\mu\, d\nu \hat{f}(\lambda, \mu, \nu) \frac{e^{i\left(\frac{\mu q}{q^2 + p^2} - \frac{\nu p}{q^2 + p^2}\right)}}{(2\pi)^2(q^2 + p^2)^2}. \]  
(50)

2.9. Tomography by hyperbolas in the plane

The family of lines
\[ \lambda - \mu x - \nu y = 0 \]  
(51)
on the plane is mapped into a family of hyperbolas
\[ \lambda - \frac{\mu}{q} - \nu p = 0, \]  
(52)
with asymptotes
\[ q = 0, \quad p = \frac{\lambda}{\nu} \]  
(53)
by the transformation
\[ (x, y) = \varphi(q, p) = \left( \frac{1}{q}, p \right). \]  
(54)

For \( \mu > 0 \) the hyperbolas are in the second and fourth quadrants, while for \( \mu < 0 \) they are in the first and third quadrants (see figure 4). When \( \mu = 0 \) or \( \nu = 0 \) they degenerate into horizontal or vertical lines, respectively.

The Jacobian
\[ J(q, p) = \left| \frac{\partial(x, y)}{\partial(q, p)} \right| = \frac{1}{q^2}, \]  
(55)
does not vanish again because \( \varphi \) is a diffeomorphism in \( \mathbb{R}^2 \). Equations (41)–(42) become
\[ \hat{f}(\lambda, \mu, \nu) = \int_{\mathbb{R}^2} dq\, dp \, f(q, p) \delta \left( \lambda - \frac{\mu}{q} - \nu p \right), \]
(56)\]and
\[ f(q, p) = \int_{\mathbb{R}^2} d\lambda\, d\mu\, d\nu \hat{f}(\lambda, \mu, \nu) \frac{1}{q^2} e^{i\left(\frac{\mu}{q} - \nu p\right)}. \]  
(57)

2.10. Hyperbolic tomography in \( \mathbb{R}^n \)

It is possible to generalize this kind of hyperbolic tomography in terms of quadratic forms. Let us consider the following tomographic map
\[ \hat{f}(\xi, \nu, \lambda) = \int d^n p\, d^n q \, \delta(\lambda - \xi \cdot q - \nu(p, q)) f(p, q), \]  
where \( p \) and \( q \) are vectors in \( \mathbb{R}^n \) and
\[ \nu(p, q) = \sum_{j=1}^{n} q_j \nu(p, p_j) \]  
(58)
is a bilinear nondegenerate diagonal form defined by a vector
\( \nu = (\nu_1, \nu_2, \ldots, \nu_n) \in \mathbb{R}^n \).

This map corresponds to the deformation of a standard multidimensional Radon transform by means of the following local diffeomorphism
\[
\phi(q, p) = \left( q_1, q_2, \ldots, q_n \right),
\]
whose Jacobian is
\[
J(q, p) = \prod_{j=1}^{n} |q_j|.
\]

Thus, the inverse map is given by
\[
f(q) = \frac{1}{(2\pi)^n} \int d^d\xi \int d^dp \int d^d\nu \delta(\nu - \lambda) \phi(\xi, \nu, \lambda)
\]
as can be derived from integration over \( \lambda \)
\[
f(q) = \frac{1}{(2\pi)^n} \int d^d\nu \int d^dp \prod_{j=1}^{n} |q_j| e^{i\nu(q - \nu \cdot p)} f(p', q')
\]
\[
= \int d^d\nu \int d^dp \prod_{j=1}^{n} |q_j| e^{i\nu(p - p \cdot q)} f(p', q).
\]

This corresponds to the higher dimensional generalization of the Bertrand–Bertrand tomography [Be87].

Notice that the distribution of hyperboloids in the plane when \( n = 2 \) is quite different from those analyzed in the previous subsection (see figure 5).

2.11. Tomography by quadrics

We remark that the above generalizations of x-ray tomograms involve integration over unbounded submanifolds. It will be interesting to generalize the Radon transform over compact submanifolds.

This can be achieved by shifting a given pattern of quadrics like
\[
q = (q - \mu) \cdot B(q - \mu) + a \cdot (q - \mu)
\]
where \( B \) is a nondegenerate symmetric operator and \( a, \mu \in \mathbb{R}^n \). A new tomographic map can be defined by
\[
\hat{f}_{ab}(\lambda, \mu) = \int d^d\nu \delta(\nu - \lambda) \cdot (q - \mu) - a \cdot (q - \mu)).
\]

This can shown by plugging the definition of the tomographic map (64) into (65)
\[
\int d^d\nu \delta(\nu - \lambda) \cdot (q - \mu)
\]
which integrating over \( \lambda \) gives
\[
\int d^d\xi f(\xi) e^{i(\xi - \mu) \cdot B(\xi - \mu) - a \cdot (\xi - \mu))}.
\]

The meaning of the above tomographic map depends on the physical character of \( B \). If we assume that \( B \) is strictly positive (elliptic case), the map corresponds to averages of \( f \) along the ellipsoids defined by equation (63). In particular, if \( a = 0 \) and all eigenvalues of \( B \) are equal to \( b^2 \) it corresponds to
integration over spheres centered at $\mu$ (see figure 6)

$$b^2(q - \mu)^2 = \lambda.$$  \hspace{1cm} (66)

The two dimensional case corresponds to trajectories of particles moving under the action of a constant magnetic field on a plane (Hall effect).

In the case that $B$ has positive and negative eigenvalues this corresponds to the hyperbolic tomography which averages at $f$ along the hyperboloids defined by the equation (63), e.g.,

$$b^2(q_1 - \mu_1)^2 - c^2(q_2 - \mu_2)^2 = \lambda.$$  \hspace{1cm} (67)

In the case of degenerated $B$ forms we have a hybrid transform. $B$ can be decomposed into a nondegenerated bilinear form and a linear form. In that case, the tomography of the linear components should be treated as the standard Radon transform, whereas the nondegenerate variables should transform as above.

Notice that the distribution of circles is quite different from those obtained by the Radon transform defined by rescaling in subsection (2.8). In that case the centers and the radius changed from one circle to another, whereas here all the circles are of fixed radius and only the center of the circles are varying by shifts. The new tomographic map makes possible a local implementation of tomography because the marginals involved in the reconstruction of $f(p,q)$ only involve integrations in the compact domain around the point $(p,q)$. The trajectories involved in the construction of the tomogram are all trajectories of a charged particle with the same energy moving in a constant magnetic field. This points out the possible applications to tomography by charged particles moving on a transversal magnetic field over samples with smaller sizes than the cyclotron radius $mv/eB$.

Finally we remark that the simplicity of the inverse formula seems to be related to the integrable character of the underlying dynamical system whose ray trajectories are involved in the construction of the tomogram. We conjecture that this is a generic issue, i.e. tomograms defined by phase space trajectories of integrable systems have simple analytic inversion formulas.

3. Tomography and coherent states

There are several representations of quantum states providing the possibility to present equivalent, but different in their form, formulations of quantum mechanics [St02]. Among them, the Wigner quasi-distribution function [Wi32] and the well-known Husimi–Kano $K-$ function [Hu40, ka56] (in this paper we have decided to keep up with the original notations of the pioneer papers on the subject). Quasi-distributions are usually referred to as phase space representations of quantum states. Another important phase space representation is related to the Sudarshan’s $\phi$ diagonal coherent-state representation [Gl63, Su63]. Interestingly, the last two phase space representations, $K$ and $\phi$, are based on the use of coherent states and allow for an interpretation in a tomographic scheme which fits nicely in the general description given above.

In the quantum case, tomography may also be cast in a quantizer-dequantizer scheme. In this sense, the Husimi–Kano function is a dequantization, and the Sudarshan’s $\phi$ is just its dual symbol. So, the coherent-state tomographic point of view provides a unifying description that encompasses also the so-called photon number tomography. Here, we limit ourselves to coherent-state (CS) tomography for a single degree of freedom, and we adopt a pedagogical style which is reminiscent of many joint papers with Volodya Man’ko.

3.1. Coherent states: main properties

In the case of a single degree of freedom, the Weyl map associates with any point $(x, \alpha)$ of the phase space of the system a unitary operator $\hat{W}(x, \alpha)$ acting on a Hilbert space $\mathcal{H}$, which can be realized in terms of square integrable functions $\psi(x)$ [Es14]. Upon switching to complex numbers $z = (x + i\alpha)/\sqrt{2}$, we recognize that $\hat{W}(x, \alpha)$ is nothing but the usual displacement operator

$$\hat{D}(z) = \exp(\sum a^\dagger z a),$$  \hspace{1cm} (68)

which acting on the vacuum Fock state $|0\rangle$, $a|0\rangle = 0$, generates the coherent state $|z\rangle$, where

$$|z\rangle = \exp\left(-\frac{|z|^2}{2}\right) \exp\left(\sum_{j=0}^\infty z_j a^\dagger a^j |0\rangle\right).$$  \hspace{1cm} (69)

We recall that the coherent states are a (over-) complete set in the Hilbert space $\mathcal{H}$. Any bounded set containing a limit point $z_0$ in the complex $z$-plane defines a complete set of coherent states containing a limit point, the coherent state $|z_0\rangle$, in the Hilbert space $\mathcal{H}$. In particular, any Cauchy sequence $\{z_k\}$ of complex numbers defines a Cauchy sequence of coherent states $\{|z_k\rangle\}$, which is a complete set. The same holds for any extracted subsequence. This completeness property holds as $\exp\left(\int |z| |\bar{f}|/2 \langle z|\psi\rangle\right)$ is an entire analytic function of the complex variable $z^*$, for any $|\psi\rangle \in \mathcal{H}$. Then

$$\langle z_k|\psi\rangle = 0 \quad \forall k \Rightarrow |\psi\rangle = 0,$$  \hspace{1cm} (70)

because $z_k^*$ is a non-isolated zero of an analytic function.

Besides, any bounded operator $\hat{A}$ may be completely reconstructed from its diagonal matrix elements $\langle z_k|\hat{A}|z_k\rangle$.

In fact, $\exp\left(\int |z| |\bar{f}|/2 \langle z|\hat{A}|z\rangle\right)$ is an analytical function of the complex variables $z^*$, $\bar{z}$, so it is uniquely determined by its value $\exp\left(\int |z| |\bar{f}|/2 \langle z|\hat{A}|z\rangle\right)$ on the diagonal $\bar{z} = z$. This is an entire function of the real variables $\Re z$, $\Im z$, which is in turn uniquely determined by its values on any set with an accumulation point.
3.2. Tomographic sets in infinite dimensional spaces

The nice properties of the coherent states previously discussed are the grounds on which CS tomography can be built. With this aim, we need to introduce a linear space $V$ and its dual $V^*$. Similar problems show up in $B(H)$, the only Hilbert space at our disposal to implement our case. As it turns out, this is the case associated with a complete set of coherent states ideal in $B(H)$. So, the tomographic set is a set of density operators. To do that, we have to interchange the role of states and observables. In other words, we can write the representation to observables or, in general, to bounded operators. Hereafter, we address the case when $z$ varies in the whole complex plane, and call CS tomography only the tomography based on the whole set of rank-one projectors $\{\tilde{P}_z\} = \{|z\rangle\langle z|\}, z \in \mathbb{C}$.

It is possible to interpret the well known Husimi–Kano $K$-symbol of a (bounded) operator $\hat{A}$ as the CS tomographic representation of $\hat{A}$:

$$K_A(z) := \langle z | \hat{A} | z \rangle = \text{Tr} \left( |z\rangle\langle z| \hat{A} \right).$$

(80)

In particular, when $\hat{A}$ is chosen as a density operator $\hat{\rho}$, the identity holds

$$\int \frac{d^2z}{\pi} \langle z | \hat{\rho} | z \rangle = \text{Tr}(\hat{\rho}) = 1.$$  

(81)

Hence, we can write the tomographic map associated to a bounded operator $\hat{A}$ reads

$$F_A(\hat{P}_z) := \langle \hat{P}_z | \hat{A} \rangle = \text{Tr}(\hat{P}_z \hat{A}) = 0$$

\(\forall \nu \in I \implies \hat{A} = 0\) and \(\hat{A} \in \mathcal{J}_2\) (76)

Then, as $\mathcal{J}_2$ is a $*$- ideal in $B(H)$, there may exist a non-zero operator $\hat{B}$, which is bounded but not Hilbert–Schmidt, such that

$$\text{Tr}(\hat{P}_z \hat{B}) = 0 \quad \forall \nu \in I \implies \hat{B} = 0$$

(77)

So, different operators may be tomographically separated only when their difference is Hilbert–Schmidt. In other words, by choosing $V = V^* = \mathcal{J}_2$ one cannot get tomographic representations of bounded, not Hilbert–Schmidt operators. Nevertheless, there exists the possibility of such a representation when the set $\{\tilde{P}_z\}$ of rank-one projectors is complete even in $\mathcal{J}_1$. Then, recalling that $\mathcal{J}_1$ is a $*$- ideal in its dual space $B(H)$, the expression $\text{Tr}(\hat{P}_z \hat{A})$ is nothing but the value of the linear functional $\text{Tr}(-\hat{A})$ in $\hat{P}_z$ and the invertibility condition holds without constraints:

$$\text{Tr}(\hat{P}_z \hat{A}) = 0 \quad \forall \nu \in I \implies 0 = \| \text{Tr}(A) \| = \| A \| \implies A = 0.$$  

(78)

So, any bounded operator can have a tomographic representation based on sets of rank-one projectors which are complete both in $\mathcal{J}_2$ and in $\mathcal{J}_1$. As it turns out, this is the case for the main tomographic sets. The rank-one projectors $\tilde{P}_z = |z\rangle\langle z|$ associated with a complete set of coherent states are complete in the Hilbert space $\mathcal{J}_2$. In particular, any Cauchy sequence $\{ |z_k\rangle \}$ generates a tomographic set $\{|z_k\rangle\langle z_k|\}$. In fact, bearing in mind the previous remark on the reconstruction of a bounded operator, it results

$$\text{Tr} \left( \hat{A} \right) = \langle z_k | \hat{A} | z_k \rangle = 0$$

\(\forall k \Rightarrow \hat{A} = 0\) and \(A \in B(H)\).  

(79)

This shows that a tomographic set of coherent state projectors is complete even in $\mathcal{J}_1$.

3.3. Coherent state tomography

The choice of tomographic sets as complete sets of rank-one projectors gives the possibility to extend the tomographic representation to observables or, in general, to bounded operators. To do that, we have to interchange the role of states and observable. We can use the self-duality of the Hilbert–Schmidt space $\mathcal{J}_2$. So, the tomographic set is a set of density states, complete in $\mathcal{J}_2$, and the invertibility of the tomographic map associated to a bounded operator $\hat{A}$ reads

$$(76)$$

$$(77)$$

$$(78)$$

$$(79)$$
which allows for the probabilistic interpretation of CS tomography. As a matter of fact [Su68], the K-symbol exists also for a number of nonbounded operators. The CS tomographic set is complete both in $L_2$ the space of Hilbert–Schmidt operators, and in $L_1$, the space of trace class operators acting on the space of states. In fact, the formulae

$$
\hat{A} = \int \frac{dz}{\pi} \frac{dz'}{\pi} \langle z \mid \hat{A} \mid z' \rangle \langle z' \mid \hat{A} \rangle
$$

and [Ma95]

$$
\langle z \mid \hat{A} \mid z' \rangle = e^{-i\int e^{\int \sum_{n,m=0} (\frac{z^n}{n!}) (\frac{z'^m}{m!}) \times \left[ \frac{\partial^{n+m}}{\partial z^n \partial z'^m} \left( e^{i\int \langle z \mid \hat{A} \mid z' \rangle \langle z' \mid \hat{A} \rangle \rangle \right) \right]_{z,z'} \rangle}
$$

show that if the tomograms $\langle z \mid \hat{A} \mid z' \rangle$ of a bounded operator $\hat{A}$ vanish for any $z \in \mathbb{C}$, then $\hat{A}$ is the zero operator.

So, a resolution of the unity exists, which allows for the full reconstruction of any density state or (bounded) operator from its CS tomograms. We are interested in the explicit determination of such a formula. Now, the Sudarshan’s diagonal coherent state representation $\phi_u(z)$ of an operator $\hat{A}$ is defined through the equation

$$
\hat{A} = \int \frac{dz}{\pi} \phi_u(z) \mid z \rangle \langle z \mid.
$$

So, to get the tomographic reconstruction formula we have to invert the well-known relation

$$
K_{A}(z') = \langle z' \mid \hat{A} \mid z \rangle = \int \frac{dz}{\pi} \phi_u(z) \langle z \mid z' \rangle \langle z' \mid \rangle = \int \frac{dz}{\pi} \phi_u(z) e^{-i\pi z z'}
$$

which follows at once from equation (84), defining $\phi_u(z)$.

This relation shows that $K_{A}(z')$ is given by the convolution product of $\phi_u(z)$ times a Gaussian function. Then, denoting with $K_{A}(u', u)$ and $\phi_u(u, v)$ the $K$ and $\phi$ symbols, with $z' = u' + iv'$ and $z = u + iv$, the Fourier transform [Sc01] of equation (85) reads:

$$
\int du' dv' K_{A}(u', u') e^{-2i\pi z (u' + v')}
= \int du' dv' \int \frac{du}{2\pi} \phi_u(u, v) e^{-2i\pi \pi (u' + v') v'} e^{-2i\pi (u' + v')(v' + z')}
$$

and we readily obtain

$$
K_{A}(\xi, \eta) = e^{-2\pi (\xi^2 + \eta^2)}
$$

from which

$$
\tilde{\phi}_A(\xi, \eta) = e^{2\pi (\xi^2 + \eta^2)}\hat{K}_{A}(\xi, \eta),
$$

that formally yields

$$
\phi_A(u, v) = \int \frac{dx}{2\pi} \frac{dy}{2\pi} e^{2\pi (\xi^2 + \eta^2)} K_{A}(\xi, \eta) e^{i\pi (u\xi + v\eta)}.
$$

The presence of the anti-Gaussian factor shows that the inverse Fourier transform of $\phi_A(\xi, \eta)$ exists only when the asymptotic decay of $K_{A}(\xi, \eta)$ is faster than the growth of $e^{-2\pi (\xi^2 + \eta^2)}$. However, the integral always exists as a distribution, as was proven in [Me65]. By virtue of this remark, we may go on and substitute the previous expression into equation (84), getting

$$
\hat{A} = \int \frac{dz}{\pi} \frac{dz'}{\pi} \tilde{G}(z') K_{A}(z'),
$$

where the operator $\tilde{G}(z')$ reads:

$$
\tilde{G}(z') = \int \frac{dz}{\pi} \int \frac{dy}{2\pi} e^{i\pi (u\xi + v\eta)} e^{2\pi \pi (\xi^2 + \eta^2)} \mid z \rangle \langle z' \mid.
$$

In other words, the CS tomographic set, like any other tomographic set, is associated with a resolution of the unity

$$
\hat{I} = \int \frac{dz}{\pi} \int \frac{dy}{2\pi} \tilde{G}(z') \langle \langle z' \rangle \rangle.
$$

In a quantizer-dequantizer scheme, the operator $\tilde{G}(z')$ is the dequantizer, while $\tilde{G}(z)$ is the quantizer. Since

$$
\mid z \rangle \langle z \mid = \int \frac{du}{\pi} \phi_{|z|}(u) \langle u \rangle \langle u \mid \langle z \rangle \langle z \mid \Rightarrow \phi_{|z|}(z') = \pi\delta(z - z'),
$$

we observe that

$$
K_G(z') = \langle z \mid \tilde{G}(z') \rangle = \int \frac{d\xi}{2\pi} \int \frac{d\eta}{2\pi} e^{-2\pi \pi (\xi^2 + \eta^2)} \hat{K}_{A}(\xi, \eta) e^{i\pi (u\xi + v\eta)}
$$

and remark that this result amounts to the orthonormality relations of the pair quantizer-dequantizer:

$$
K_G(z') = \langle z \mid \tilde{G}(z') \rangle = \pi\delta(z - z').
$$

If one exchanges the roles in the pair, and bears in mind the definition of $G(z)$, one recovers the dual symbol of an
operator as its Sudarshan’s symbol $\phi$,

$$\text{Tr} \left( \hat{G}(z')\hat{A} \right) = \int \frac{d^2z}{2\pi} e^{i[-z\xi' - q\eta']} K_A(z, \eta)$$

$$\times e^{i[z\xi' + q\eta']/4} \phi_A(z, \eta) = \int \frac{d^2z}{2\pi} e^{i[-z\xi' - q\eta']} \phi_A(z, \eta) = \phi_A(z'). \quad (97)$$

In this dual theory, the definition of the Sudarshan’s symbol as diagonal representation, equation (84), appears as a reconstruction formula, the quantizer being $\tilde{P}$.

In a tomographic picture of quantum mechanics, this gives the possibility of representing in tomographic, i.e., ‘inner’, terms, quantities such as expectation values of observables

$$\text{Tr} \left( \hat{A}_\rho \hat{A} \right) = \int \frac{d^2z}{\pi} K_\rho(z) \text{Tr} \left( \hat{G}(z)\hat{A} \right)$$

$$= \int \frac{d^2z}{\pi} K_\rho(z) \phi_A(z). \quad (98)$$

We remark that, in the context of the Agarval–Wolf operator ordering theory [Ag68, Ma95], the $K$ and $\phi$ symbols, appearing in our direct and dual reconstruction formulae, are related to the Wick (i.e., normal) and anti-Wick ordering, respectively. Of course, if one insists on requiring only the use of CS tomographic representation, one needs to introduce a star-product by means of an integral kernel:

$$\text{Tr} \left( \hat{A}_\rho \hat{A} \right) = K_{\rho A}(z) = (K_\rho * K_A)(z)$$

$$:= \int \frac{d^2z_1}{\pi} \frac{d^2z_2}{\pi} K_\rho(z_1) K_A(z_2) Q(z_1, z_2, z)$$

$$Q(z_1, z_2, z) = \text{Tr} \left( \hat{G}(z_1)\hat{G}(z_2)\tilde{P} \right). \quad (99)$$

More details on star-product kernels are contained in a recent work with Volodya Man’ko [Ib13]. We conclude by observing that CS tomography can be generalized by using coherent states and nonlinear coherent states of deformed oscillators, including $q$-oscillators. This generalization was analyzed in [Ma08].

4. Tomography and the algebraic description of quantum systems

As discussed in the introduction, the algebraic description of quantum systems based on the theory of $C^*$-algebras emerges from an analysis of the fundamental structures needed to describe physical systems. The tomographic description of them has been started recently in [Ib13], (see also [Lo14] and references therein).

Jordan algebras were introduced by P Jordan as an attempt to unfold the algebraic structure of quantum systems, but it was only after the work of Alfsen and Schultz [Al98] that the exact relation with the theory of $C^*$-algebras was established. Recently, this relation was revisited by Falceco et al [Fa13, Fa13b] and the relation between $C^*$-algebras and Lie–Jordan Banach algebras was clearly established. This equivalence was used too to describe the theory of reduction of $C^*$-algebras described in terms of Lie–Jordan–Banach algebras.

In this section the first steps towards a tomographic description of quantum systems based on $C^*$ and Lie–Jordan algebras will be established. One of the main outcomes of the theory is that it fits nicely with the tomographic description based on groups, as will be shown in what follows. Thus, we will review first the basic notions from the theory of $C^*$ and Lie–Jordan algebras that will be needed, and after this the tomographic description of a quantum system described by a Lie–Jordan algebra and a group representation will be succinctly described.

4.1. $C^*$-tomography

We will consider a quantum system described by a unital $C^*$-algebra $\mathcal{A}$, whose self-adjoint part constitutes the Lie–Jordan–Banach algebra of observables of the theory. The states of the system are normalized positive functionals $\rho: \mathcal{A} \to \mathbb{C}$,

$$\rho(1) = 1, \quad \rho(a^*a) \geq 0, \quad \forall a \in \mathcal{A}$$

and they determine a weak*-compact subset $S(\mathcal{A})$ of the topological dual $\mathcal{A}^*$. Given $a \in \mathcal{A}$, the number $\rho(a)$ is the expected value of the observable measured in the state $\rho$, also denoted as $\langle a \rangle_\rho$. Hence, for each self-adjoint element $a \in \mathcal{A}$, we may define a continuous affine function $\hat{a}: S(\mathcal{A}) \to \mathbb{R}$, $\hat{a}(\rho) = \rho(a)$. The Kadison theorem [Ka51] states that the correspondence $a \mapsto \hat{a}$ is an isometric isomorphism from the self-adjoint part of $\mathcal{A}$ onto the space of all continuous affine functions on $S(\mathcal{A})$. Notice that the Hilbert space picture of the system, once a state is given, can be recovered by means of the GNS construction [Na72].

If we consider now the general background of tomography as stated in section 1.2, we may consider that the space of states is a subset of the linear space $V = \mathcal{A}$. Moreover, because $\mathcal{A} \subset \mathcal{A}^*$, then we may think that the elements $a$ in the dual $V^*$ are going to lie in $\mathcal{A} \subset V^*$. Thus the tomographic description of the state $\rho$ of $\mathcal{A}$ will consist of assigning to this state a probability density function $W_\rho$, that we will call ‘tomogram’, on some auxiliary space $\mathcal{N}$ such that, given $W_\rho$, the state $\rho$ can be reconstructed unambiguously.

Hence we consider a family of elements in $\mathcal{A}$ parameterized by an index which can be discrete or continuous, the elements of $\mathcal{N}$, or, in other words, consider a map $U: \mathcal{N} \to \mathcal{A}$ and we will denote by $U(x)$ the element in $\mathcal{A}$ associated with the element $x \in \mathcal{N}$. The family $\{U(x)| x \in \mathcal{N}\}$ will be called a tomographic set if it separates states, i.e., given $\rho_1, \rho_2 \in S(\mathcal{A})$, if $\rho_1 \neq \rho_2$, then $\exists x \in \mathcal{N}$ such that $\langle \rho_1, U(x) \rangle \neq \langle \rho_2, U(x) \rangle$.

Given a state $\rho$ and a tomographic set $U$, we will call the function $F_\rho: \mathcal{N} \to \mathbb{C}$, defined as (recall equation (1)):

$$F_\rho(x) = \langle \rho, U(x) \rangle,$$

the sampling function of $\rho$ with respect to $U$. 
Let us assume that \( \mathcal{N} \) is a topological space with a positive Borel measure \( \mu \) on it. We will also assume that the map \( U \) is continuous and integrable in the sense that for any \( \rho \in S(\mathcal{A}) \), the sampling function \( F_\rho: \mathcal{N} \to \mathbb{C} \) is integrable, that is, \( F_\rho \in L^1(\mathcal{N}, \mu) \). The auxiliary space \( \mathcal{N} \) (and the measure \( \mu \) on it) used in the theory could depend on the specific problem. Later on a rather general way of selecting the auxiliary spaces by means of groups and their unitary representations will be discussed (see section 4.3).

In order to guarantee that the assignment \( \rho \mapsto F_\rho \) is invertible, we will assume that there exists another map \( D: \mathcal{N} \to \mathcal{A} \) which is integrable in the sense that for any \( a \in \mathcal{A} \) the function \( G_\rho(x) := \langle D(x), a \rangle \) is integrable, and such that

\[
\langle D(x), U(x') \rangle = \delta(x, x'), \quad x, x' \in \mathcal{N},
\]

where \( \delta(x, x') \) is the delta distribution along the diagonal on \( \mathcal{N} \times \mathcal{N} \), that is:

\[
\phi(x) = \int_\mathcal{N} \delta(x, x') \phi(x') d\mu(x'),
\]

where \( \phi \) is a continuous function with compact support on \( \mathcal{N} \). If a map \( D \) exists satisfying the property (101) we will say that \( U \) and \( D \) are biorthogonal.

If we denote now by \( \hat{\rho}(x) = F_\rho(x) = \langle \rho, U(x) \rangle \) and by

\[
\hat{\phi} = \int_\mathcal{N} \phi(x) D(x) d\mu(x),
\]

with \( \phi \) an integrable function, then it is easy to see that

\[
\hat{\phi}(x) = \phi(x) \quad \text{and} \quad \hat{\rho} = \rho.
\]

It is also noticeable that because

\[
\int_\mathcal{N} F_\rho(x) d\mu(x) = \int_\mathcal{N} \rho \langle U(x), \mu(x) \rangle
\]

it is convenient to assume that

\[
\int_\mathcal{N} U(x) d\mu(x) = 1.
\]

If \( U(x) \) satisfies this, then we will say that \( U(x) \) is normalized. In such a case it is clear that

\[
\int_\mathcal{N} F_\rho(x) d\mu(x) = 1.
\]

We may recast the previous theorem by computing first the \( \rho \) map and later the \( \hat{\rho} \) map on \( F_\rho \):

\[
\hat{F}_\rho = \int_\mathcal{N} D(x) F_\rho(x) d\mu(x),
\]

then if we apply the \( \hat{\rho} \) map first, we get

\[
\hat{F}_\rho(x') = \langle \hat{F}_\rho(x), U(x') \rangle
\]

\[
= \int_\mathcal{N} F_\rho(x) \langle D(x), U(x') \rangle d\mu(x)
\]

\[
= F_\rho(x'), \quad \forall x' \in \mathcal{N}.
\]

We may also define another function \( F_\rho(x, x') \) depending on two arguments instead of one:

\[
F_\rho(x, x') = \langle \rho, U(x)\rho U(x') \rangle \quad \forall x, x' \in \mathcal{N}.
\]

We will encounter in many situations the presence of a group in the theory whose states we want to describe tomo-graphically. This group could be a group of symmetries of the dynamics of the system or a group which is describing the background of the theory. In any of these circumstances we will assume that there is a Lie group \( G \) acting on the \( C^* \)-algebra \( \mathcal{A} \), i.e., we have a strongly continuous map \( T: G \to \text{Aut}(\mathcal{A}) \) such that

\[
T_e = 1, \quad T_{g_1} T_{g_2} = T_{g_1 g_2} \quad \forall g_1, g_2 \in G.
\]

In such a case we will need to assume that the group \( G \) acts on the auxiliary spaces used to construct the tomo-graphic picture. Thus, the group \( G \) will act on \( \mathcal{N} \), and such action will be simply denoted as \( x \mapsto g \cdot x, \ x \in \mathcal{N} \).

The natural compatibility condition for a tomo-graphic map \( U: \mathcal{N} \to \mathcal{A} \) to be compatible with the group \( G \) present in the theory is equivariance, i.e.,

\[
U(g \cdot x) = T_g(U(x)), \quad \forall x \in \mathcal{N}, \ g \in G.
\]

This could be interpreted by saying that if the parameters \( x, x' \) parametrizing two sampling elements \( U(x) \) and \( U(x') \) in \( \mathcal{A} \), are related by an element \( g \) of the group, i.e., \( x' = g \cdot x \), then the two sampling observables \( U(x), U(x') \) are also related by the same element of \( G \).

Under these conditions, it is easy to conclude that the sampling function \( F_\rho \) corresponding to the state \( \rho \) satisfies the following:

\[
F_\rho(g \cdot x) = F_{T^{-1}_g \rho}(x),
\]
because
\[
F_\rho(g \cdot x) = \left\langle \rho, U(g \cdot x) \right\rangle = \left\langle \rho, T_\rho(U(x)) \right\rangle = \left\langle T_\rho^* \rho, U(x) \right\rangle = F_{T_\rho^* \rho}(x),
\]
(107)
where \(T_\rho^* \rho\) denotes the adjoint action of \(G\) on \(A\). Notice that if \(\rho\) is an invariant state, \(T_\rho^* \rho = \rho\) then the corresponding sampling function will be invariant too.

\[
F_\rho(g \cdot x) = F_\rho(x), \quad \forall g \in G, \quad x \in \mathcal{M}.
\]
(108)

We will also consider that situation where the group \(G\) acts on the space \(M\) defining the space of classical functions whose tomograms we would like to obtain. We will denote again such action by \(y \mapsto g \cdot y, \ y \in M\). The generalised Radon transform \(R: \mathcal{N} \rightarrow \mathcal{F}(M)\) should be equivariant, this is

\[
R(g \cdot y) = g_s R(y),
\]
(109)
where \(g_s\) indicates now the natural action induced on the space \(\mathcal{F}(M)\) in the dual of the space of functions on \(M\), by the action of \(G\) on \(M\). More explicitly

\[
\left\{ g_s(R(y)), F \right\} = \left\{ R(y), g^s F \right\}
\]
and
\[
g^s F(x) = F(g \cdot x).
\]
(110)

Now, if \(R\) is actually a generalised Radon transform and \(W_\rho\) denotes the tomogram of the state \(\rho\), we have: \(W_\rho(g \cdot y) = R(g \cdot y) = W_\rho(\rho, F_\rho) = \left\langle g_s R(y), F_\rho \right\rangle = \left\langle R(y), g^s F_\rho \right\rangle = \left\langle R(y), F_{g^s \rho} \right\rangle = W_{g^s \rho}(y).
\)
(111)

Then we conclude this discussion by observing that if \(\rho\) is an invariant state, the tomogram defined by it is actually invariant:

\[
W_\rho(g \cdot y) = W_\rho(y), \quad \forall g \in G.
\]
(112)

### 4.3. Unitary group representations on C*-algebras

We will discuss now a particular instance of the tomographic programme discussed above where a Lie group \(G\) plays a paramount role. We will find this situation, for instance, in spin tomography where the group \(G\) will be the group \(SU(N)\), but such a situation is found also in standard homodyne tomography, which could be understood in similar terms with the group \(G\) being the Heisenberg–Weyl group.

Now we will assume that the auxiliary space \(\mathcal{N}\) is a group \(G\) and the tomographic map \(U: G \rightarrow A\) is provided by a continuous unitary representation of \(G\) on \(A\), that is, \(U(g)^* = U(g)^{-1} = U(g^{-1})\) is a unitary element in the C*-algebra \(A\), and \(U(g_1 g_2) = U(g_1)U(g_2)\) and \(U(e) = 1\). Then we may denote by \(T: G \rightarrow \text{Aut}(A)\), the action of \(G\) on \(A\) by the inner automorphism given by

\[
T_\rho(a) = U(g)^* \cdot a \cdot U(g), \quad a \in A, \ g \in G.
\]

Then we can see immediately that we have the equivariance property for the tomographic map with respect to the action of \(G\) on itself by conjugation:

\[
U(g^{-1} h g) = U(g^{-1}) \cdot U(h) \cdot U(g) = T_\rho(U(h)), \quad g, \ h \in G.
\]
(113)

The sampling function corresponding to the state \(\rho\) is given by

\[
F_\rho(g) = \langle \rho, U(g) \rangle,
\]
(114)
and we may check that the map \(F_\rho\): \(G \rightarrow \mathbb{C}\) is a positive semidefinite map in the sense that the map \(F_\rho(g, h)\) of two arguments defined as

\[
F_\rho(g, h) = F_\rho(g^{-1} h) \quad g, \ h \in G,
\]

is positive semidefinite, i.e. \(\forall N \in \mathbb{N}, \xi_1, \xi_2 \in \mathbb{C}, \ g_i \in G, \ i = 1, \ldots, N\), then

\[
\sum_{i,j=1}^{N} \xi_i \xi_j F_\rho(g_i^{-1} g_j) \geq 0.
\]
(115)

Naimark's theorem [Na72] establishes that given a positive semidefinite function \(F\) on a group \(G\), there exists a Hilbert space \(H_F\), a continuous unitary representation \(U_F\): \(G \rightarrow U(H_F)\) and a vector \(|0\rangle \in H_F\) such that

\[
F(g) = \langle 0 | U_F(g) | 0 \rangle.
\]
(116)

The relation between the state \(|0\rangle \langle 0| = \rho_F\), the representation \(U_F\), the original state \(\rho\) and the original representation \(U\) has been discussed recently [Ib11].

In order to now define the generalised Radon transform that will describe the tomogram corresponding to the state \(\rho\), we will consider now the Lie algebra \(\mathfrak{g}\) of the group \(G\) and the auxiliary space \(g \times \mathbb{R}\). In \(g \times \mathbb{R}\) we have defined the natural extension of the standard exponential map \(\exp: g \times \mathbb{R} \rightarrow G\) given by \(\exp(x, s) = \exp(xs)\).

The unitary representation of \(G\) on \(A\) defines a Lie algebra homomorphism from \(g\) into \(A_{sa}\), where \(A_{sa}\) denotes the self-adjoint part of \(A\), that is, \(A_{sa} = \{ a \in A | a^* = a \}\).

Given any \(\xi \in g\), we denote by \(\hat{\xi}\) the element of \(A_{sa}\) defined as:

\[
\hat{\xi} = -i \frac{d}{ds} \left. U \left( \exp(is\xi) \right) \right|_{s=0} = -i \frac{d}{ds} \left. U \left( \exp(x\xi, s) \right) \right|_{s=0}.
\]
(117)

Clearly \(\hat{\xi}^* = \hat{\xi}\) and

\[
[\hat{\xi}, \hat{\zeta}] = \left[ \xi, \zeta \right], \quad \forall \xi, \zeta \in g.
\]
(118)

### 4.4. The GNS construction and unitary group representations on C*-algebras

Given the state \(\rho\), the GNS construction allows us to represent the C*-algebra \(A\) as operators acting on a Hilbert space \(H_\rho\). To be precise, consider the Hilbert space \(H_\rho\) obtained as the completion of the space \(A/J_\rho\), where \(J_\rho = \ker \rho\) is the
Gelfand ideal defined by $\rho$, with respect to the inner product, defined as:

$$
\langle [a], [b] \rangle = \rho(a^*b),
\forall [a] = a + J_\rho, [b] = b + J_\rho \in A/J_\rho.
$$

(119)

Then there is a natural representation $\pi_\rho$: $A \to B(H)$ given by:

$$
\pi_\rho(a) = [a \cdot b], \quad \forall [b] \in H_\rho.
$$

(120)

The unitary representation $U$: $G \to \text{Aut}(A)$ of the group $G$ becomes a unitary representation $U_\rho$ of $G$ on $H_\rho$ by means of $U_\rho = \pi_\rho \circ U$, i.e., $U_\rho: G \to U(H_\rho)$ is the map defined by $U_\rho(g) = \pi_\rho(U(g))$.

Notice that because $U$ is unitary, $U(g)$ is a unitary element in $A$, then $\pi_\rho(U(g))$ is a unitary operator on $H_\rho$. In fact, for all $[a], [b] \in H_\rho$ we have:

$$
\langle U_\rho(g)[a], U_\rho(g)[b] \rangle_\rho = \langle \pi_\rho(U_\rho(g))[a], \pi_\rho(U_\rho(g))[b] \rangle_\rho
$$

(121)

$$
= \rho \left( \left( U_\rho(g)a \right)^* U_\rho(g)b \right)
= \rho \left( a^*b \right) \langle [a], [b] \rangle_\rho. 
$$

(122)

If we consider now the induced map $g \to A_\rho$, we will obtain that the element $\xi \in g$ will be mapped by the representation $\pi_\rho$ into a self-adjoint operator on $H_\rho$. We will denote the operator defined in this way by $\xi_\rho$, that is:

$$
i_\rho^* \langle [a] \rangle = \frac{d}{ds} U_\rho(\exp(s\xi))[a] \bigg|_{s=0}
= \frac{d}{ds} \pi_\rho(U(\exp(s\xi))[a]) \bigg|_{s=0}
$$

(123)

$$
= \left. \frac{d}{ds} U(\exp(s\xi))a \right|_{s=0} \cdot a = \left[ i^* \xi a \right].
$$

(124)

Because of Stone’s theorem, we know that there exists a unique strongly continuous one-parameter group of unitary operators $U_\xi^t$ on $H_\rho$ such that

$$
\frac{d}{ds} U_\xi^s [a] \bigg|_{s=0} = i_\rho^* \langle [a] \rangle,
$$

(125)

thus:

$$e^{i_\rho^*} = U_\xi^t = U_\rho(\exp(s\xi)) = \pi_\rho \circ U(\exp(s\xi)).
$$

(126)

Finally, the spectral theorem applied to the self-adjoint operators $\xi_\rho$ asserts that there is a Borelian spectral measure $E_{\xi_\rho}$ in the real line such that

$$\hat{\xi}_\rho = \int \lambda \ dE_{\xi_\rho}(\lambda),
$$

(127)

hence

$$U_\xi^t = \int e^{i\lambda t} dE_{\xi_\rho}(\lambda).$$

(128)

Now, we will consider as auxiliary space $N$ the space $g \times \mathbb{R}$, and we will define the map $R: g \times \mathbb{R} \to (F(G))'$ as follows:

$$R(\xi; \lambda)(F) = \frac{1}{(2\pi)^2} \int \exp(-i\lambda s) d(\xi) ds.
$$

(129)

To be precise, the map $R$ is defined from $g \times \mathbb{R}$ into the space of continuous functions on the exponential of $g$, $\exp(g) \subset G$. For groups such that $\exp(g) = G$, i.e., exponential groups, we have the map written above.

Then we will call the function $R(\xi; \lambda)(F)$ corresponding to the tomographic function $F_\rho$ defined by the state $\rho$, the tomogram of $\rho$ and it will be denoted by $W_\rho(\xi; \lambda)$. Notice that we may fix $\lambda = 1$ to get:

$$W_\rho(\xi) = \frac{1}{(2\pi)^2} \int \exp(-i\xi s) d(\xi) ds.
$$

(130)

Notice that if we compute the inverse Fourier transform of the tomogram $W_\rho$, we have:

$$F_\rho(\exp(s\xi)) = \int e^{i\lambda t} W_\rho(\xi; \lambda) d\lambda
$$

(131)

and if we consider now that

$$F_\rho(\exp(s\xi)) = \langle \rho, U(\exp(s\xi)) \rangle
= \langle 0| U_\rho(\exp(s\xi)) |0 \rangle
= \langle 0| e^{i\xi t} dE_{\xi_\rho}(\lambda) |0 \rangle
$$

(132)

Then if the measure $\mu_{\xi_\rho} = \langle 0| dE_{\xi_\rho} |0 \rangle$ is absolutely continuous with respect to the Lebesgue measure, we will have that $\mu_{\xi_\rho}(\lambda) = W_\rho(\xi; \lambda) d\lambda$, and $W_\rho(\xi; \lambda)$ will be the Radon–Nikodym derivative of $\mu_{\xi_\rho}$ with respect to $d\lambda$. Hence, we have obtained that, under these conditions, the tomogram $W_\rho$ of the state $\rho$ can be written as:

$$W_\rho(\xi; \lambda) = \frac{d\mu_{\xi_\rho}}{d\lambda},
$$

(133)

where $d\mu_{\xi_\rho}/d\lambda$ denotes the Radon–Nikodym derivative of $\mu_{\xi_\rho}$ with respect to the Lebesgue measure $d\lambda$.

Finally, suppose that $\omega$ is a density operator on $H_\rho$. We will define its tomographic function by $F_\omega(g) = \text{Tr}(\omega U_\rho(g))$ and its tomogram $W_\omega(\xi; \lambda)$ as:

$$W_\omega(\xi; \lambda) = \frac{1}{(2\pi)^2} \int \exp(-i\lambda s) F_\omega(\exp(s\xi)) ds.
$$

(134)
Then computing the inverse Fourier transform of $W_\omega (\xi; \lambda)$ we will get:

$$F_\omega (\exp (s \xi)) = \int e^{i s \xi} W_\omega (\xi; \lambda) d\lambda.$$ 

A simple computation shows that:

$$W_\omega (\xi; \lambda) = \frac{1}{(2\pi)^3} \int e^{i s \xi} F_\omega (\exp (s \xi)) ds = \frac{1}{(2\pi)^2} \int e^{i s \xi} Tr (\omega U_\lambda (\exp (s \xi))) ds = \frac{1}{(2\pi)^2} \int e^{-i s \xi} \omega U_\lambda (\exp (s \xi)) ds \bigg|_{\xi = \lambda} \omega$$

$$= \int e^{-i s \xi} \omega (2\pi) \delta (\lambda - \xi) ds = \int e^{-i (\lambda - \xi)} ds.$$

which is the formula for the tomogram $W_\omega$ that resembles closely the classical Radon transform, equation (29), in the affine language.
