An electrochemically neutralized energy-assisted low-cost acid-alkaline electrolyzer for energy-saving hydrogen generation

This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
1. Introduction

Multifunctional devices are objects able to achieve a combined set of properties, such as electrical, mechanical, optical, or thermal and that are able to convert energy from one type to another. Electronic components, sensors, energy harvesting and water splitting devices, catalysts are examples of devices receiving great interest from both the scientific community and industries, and that require the fusion of multiple properties into one object. More recently, robotics, automobile, artificial intelligence (AI), Internet of Things (IoT) are increasingly relying on multifunctional devices that are smaller, faster, high performance, and processable into 3D shapes by 3D printing.

The rapid technology growth in these domains reflects the unprecedented advances in materials science and engineering, and urges further material evolution on both functional and structural aspects. To fulfil these versatile functionalities and realize the promises of Industry 4.0, two-dimensional (2D) nanomaterials which exhibit unique intrinsic properties have become an indispensable choice.

2D nanomaterials are a class of crystalline materials in the form of a single-layer or a few-layers lamellar structure. They possess a high lateral diameter to thickness aspect ratio as well as stronger in-plane interatomic interactions than in their stacking, out-of-plane direction. The year of 2004 witnessed the successful exfoliation of monolayer graphene by Geim and Novoselov,\(^1\) which led to the renaissance of the study of 2D nanolayer materials. Since then, remarkable properties such as large surface area, tunable surface functionality, strong mechanical strength, excellent thermal and electric conductivities have been successively found in graphene.\(^2\)\(^-\)\(^11\) Notably, these outstanding properties in graphene such as its ultrahigh carrier mobility of \(10^4\) cm\(^2\) V\(^{-1}\) s\(^{-1}\), thermal conductivity of about 4000 W m\(^{-1}\) K\(^{-1}\) and high Young’s modulus of about 1 TPa are demonstrated within the in-plane direction, which are significantly suppressed along the out-of-plane direction.\(^12\)\(^-\)\(^14\)

Preparation of 2D nanomaterials is commonly achieved by top-down approaches where bulk layered materials are exfoliated into nanosheets for example using mechanochemical processes, or by bottom-up synthesis from molecular precursors. More recently, the prosperous studies on graphene have expanded to the emergence of novel 2D nanomaterials of other chemistries.\(^15\)

For example, transition metal dichalcogenides (TMDCs), of formula of MX\(_2\), where M is the transition metal like Mo, Ti, V, Hf, W, etc., and X represents the chalcogen such as S, Te and Se, have been found to exhibit tunable bandgaps for semiconducting and optoelectronic related applications.\(^5\)\(^,\)\(^16\)\(^,\)\(^17\) In addition, 2D hexagonal boron nitride (h-BN), an isomorph of graphene, also attracts considerable attention. Indeed, different from the conjugated...
valence electrons in graphite, the distinct electronegativity of B and N atoms confers electrical insulation to h-BN. Thanks to their outstanding electrical insulation, in-plane thermal conductivity of about 400 W m⁻¹ K⁻¹, thermal stability at temperatures higher than 600 °C, mechanical robustness as well as chemical inertness, 2D h-BN becomes very useful for microelectronics, as reinforcing nanofilms, field effect transistors (FETs), among others.\textsuperscript{19,20} Moreover, the family of MXenes, which represents 2D transition metal carbides, nitrides and carbonitrides, has grown rapidly over the past decade.\textsuperscript{21-23} MXenes have a general formula of $\text{M}_n\text{X}_n\text{X}_n\text{T}_n$ ($n = 1-3$), where M is a transition metal such as Ti, Ta, V, Zr, etc., X is carbon or nitrogen, and T represents surface functional groups. Since the report of $\text{Ti}_3\text{C}_2$ in 2011, there have been more than 30 different MXenes synthesized, which typically exhibit metallic conductive property because of the existence of conductive vertical and metal layers in the 2D structure and a hydrophilic nature due to the surface terminations like hydroxyl, oxygen or fluorine.\textsuperscript{24-25} The wide chemical and structural variety of MXenes enables their promising applications for energy storage, electromagnetic interference (EMI) shielding, catalysis, sensors and so on.

The diverse crystal structures and blooming functionalities in 2D nanomaterials provide great opportunities to establish optimized material performances for realistic device applications. Indeed, tailored microstructures with local orientation of 2D nanomaterials could be an efficient pathway to unlock their potential and transpose their outstanding nanoscopic properties to the macroscopic scale. Controlling the assembly of anisotropic particles into hierarchical structures is a way to induce new, unique macroscopic properties that cannot be obtained in random configurations. This effect is well demonstrated in natural materials, which have evolved complex microstructures with local alignment over the years, providing us an inspirational gallery for structural design and fabrication.\textsuperscript{26-30} By mimicking these natural microstructures, many advanced artificial materials exhibiting attractive properties and functions have been realized (Fig. 1). We can imagine that if these delicate local orientations can be precisely controlled and reasonably combined with various 2D nanomaterial combinations, any set desired functionalities could be realized.

The capability of precisely controlling the alignment of 2D nanomaterials has always been exciting while rather challenging. **Fig. 2a** displays the statistical number of publications on 2D nanomaterials and 2D nanomaterials with aligned structure from 2011 to 2021. In the past ten years, there has been a significantly increase in 2D nanomaterial-related studies, reflecting the promises of 2D nanomaterials for material development. The publications related to aligned 2D nanomaterials also exhibit a growing tendency especially in the latest years. However, these studies only comprise 7.67% of the
total research on 2D nanomaterials (Fig. 2b), indicating available, vacant area for further research. Classifying the alignment of the 2D nanomaterials as vertical, horizontal, arbitrary and heterogeneous microstructures, it appears that vertical and horizontal alignment account for most research interest (Fig. 2c).

From these recent research, one major observation is that the lateral size of the 2D nanomaterials and their orientations greatly impact the properties at the microscopic and macroscopic scales. These results have already been reviewed and summarized by others. For example, Luo et al. compared the strategies of improving photocatalytic performances by assembling functional architectures with 2D nanomaterials and analyzed its role in enhancing the energy conversion efficiency. Zhang et al. reviewed the growth mechanism of vertically aligned graphene nanosheet arrays (VAGNAs) and discussed their properties for electrochemical energy applications. Yaraghi et al. focused on fabrication methods and structures of biomimetic structural materials with brick-and-mortar and helicoidal architectures. Cao et al. provided a survey on low-dimensional materials for electromagnetic (EM) applications and discussed the strategy of constructing well-aligned 2D nanosheets. Tan et al. stressed the advances of vertically aligned nanosheets (VANS) for batteries. Furthermore, Huang et al. pointed out that the aligned carbon-based electrodes (ACBES) can greatly enhance the battery power density due to the combined advantages of aligned structure and carbon-based materials. Shao et al. emphasized the role of freeze casting technique in the formation of well-controlled biomimetic porous materials from low-dimensional building blocks. Moreover, Lei et al. reviewed the specific role of vertically aligned structures in polymer composite materials for multiple applications. Zhang et al. provided synthesis and modification methods of polymer composites with aligned 2D nanomaterials and their potential applications. In most of the reviews, the controlled orientation mainly focused on a single orientation type such as vertical or horizontal, throughout the bulk material, or limited fabrication methods for specific target application. A systematic review on diverse orientation design of 2D nanomaterials and their augmented properties is thus still lacking.

In view of controlling the microstructural local alignment of 2D nanomaterials for improving performances, it is therefore timely to review the up-to-date development on this topic and to propose a vision on how to leverage the diversity in chemistry and properties of 2D nanomaterials to yield multifunctional high-performance devices. Herein, we review the most recent research on controlled local orientation of 2D nanomaterials for functional designs and envision future prospects. The outline of this review is presented in Fig. 3. First, in this introduction, the...
background for studying 2D nanomaterials and the inspirations to develop the locally aligned microstructures are provided. In the next section, we provide examples that demonstrate how oriented 2D nanomaterials can enhance the performances for selected applications, namely sensing, thermoelectrics and electrochemical energy harvesting. Following are reviewed the fabrication methods for horizontal, vertical, heterogeneous, and arbitrary aligned microstructures. To bridge the gap between microstructural and 3D macroscopic devices, the fourth section of this review discusses how 3D printing can contribute to achieve locally aligned structures and what are its capability to build macroscopic architectures combining multiple chemistries. Finally, we anticipate the potential of controlled alignment of 2D nanomaterials for functional designs and applications and discuss remaining challenges, for the fabrication of next-generation smart multifunctional devices.

2. Oriented 2D nanomaterials for functional applications

This section provides examples from the literature, that demonstrate why orienting 2D nanomaterials purposely is key for achieving high performance in macroscopic components. We specifically selected a few functional applications that we see as the most promising for future energy and sustainability enhancement, and that are under intense research in the materials community. These are sensing, thermoelectrics and electrochemical energy harvesting. The reader is then invited to draw analogies for other applications of their interest, where aligned and specifically oriented 2D nanomaterials could enhance the properties and functionalities of materials and devices.

2.1. Sensing

A sensor is a signal generator that captures physical input from its working environment and converts it into a readable output. An ideal sensor should possess high sensitivity, selectivity and stability.\textsuperscript{15,61,62} The sensitivity is typically determined by the ability of materials to respond to environmental stimuli such as optical, thermal, electrical, mechanical or chemical variations.\textsuperscript{63,64} 2D nanomaterials, with their exceptional surface properties, are promising candidates for sensing applications. Controlling the alignment of 2D nanomaterials has proved to be beneficial in sensing mainly because it can improve i) the density of exposed active sites, ii) the surface-to-volume ratio, and iii) the charge transfer within the oriented material.\textsuperscript{65} Gas sensing and photodetection are among the most extensively studied sensing applications using 2D nanomaterials. In gas sensing applications, the mechanism consists in transforming chemical potential into electrical current density through gas molecules adsorption, where the resistance change is closely related to chemical reactions occurring at the surface of the nanomaterials. For photodetection, the mechanism is to convert an incident optical signal into an electrical signal based
on optical responsivity of the material. Taking gas sensing as an example, the sensitivity (S) is defined as:

\[ S(\%) = \frac{\Delta I}{I_0} \times 100 \]  

(1)

where \( \Delta I \) is the gas-induced current change and \( I_0 \) is the current of the sensor without gas. Various 2D nanomaterials such as MXene, TMDCs, graphene and phosphorene have been used to absorb gases like \( \text{NO}_2 \), \( \text{CO}_2 \), \( \text{NH}_3 \), and \( \text{H}_2\text{S} \). Figure 4 illustrates the \( \text{NO}_2 \) gas sensing properties in MoS\(_2\) films with horizontal, vertical and mixed alignment structures. During gas sensing, the gas adsorption capability is closely related to the binding energy between the active sites and the gas molecules. The exposed edge sites with high surface energy in vertically aligned MoS\(_2\) provided high adsorption, while the adsorption in basal plane of horizontally aligned was much lower. Meanwhile, the resistance of vertically aligned film was significantly increased, which was attributed to the dominated carrier transport within the van der Waals gaps in cross plane direction. As a result, the vertically aligned MoS\(_2\) film allowed a 5-times higher resistance variation and could even detect 0.1 ppm of \( \text{NO}_2 \) gas when the maximum amplitude of electrical responses (\( \Delta R/R_0 \)) was 0.2%, which was impossible in the horizontally aligned film (Fig. 4f). In another example, Jiang et al. reported the \( \text{H}_2\text{S} \) gas sensing response of Fe\(_3\)O\(_4\)/graphene nanosheets with horizontal and vertical alignments (Fig. 4g and 4h). The alignment was induced by controlled magnetic field assembly under a directed-flow and will be described in the section 3 of this review. The vertically aligned Fe\(_3\)O\(_4\)/graphene nanosheets exhibited higher sensitivity (~450 absorption units to 15 ppm \( \text{H}_2\text{S} \)) than the horizontally aligned ones (~350 absorption units to 23 ppm \( \text{H}_2\text{S} \)) at a working temperature of 190 °C (Fig. 4j). This improved sensing capability in response to \( \text{H}_2\text{S} \) gas could be attributed to a larger contact area as well as less resistance to the target gas flow. Islam et al. also observed high sensitivity to \( \text{NO}_2 \) gas in vertically aligned MoS\(_2\) layers. The sensitivity was about 160-380% within a gas concentration of 5-30 ppm, demonstrating much higher response compared with the horizontally aligned layers. The higher sensitivity in vertical alignment could be attributed to the exposed edge sites with sufficient dangling bonds, leading to high chemical reactivity and adsorption capability. These few, selected examples illustrate how the orientation of 2D nanomaterials can be utilized to boost the performance of sensing devices.
2.2 Thermoelectrics

To tackle the increasing global energy demand, the ability of harvesting electric energy from waste heat from the thermoelectric effect has attracted considerable attention.\textsuperscript{88-91} The thermoelectric effect refers to the phenomenon by which a temperature difference is directly converted into an electric voltage and vice versa. The process of voltage generation from a temperature difference is known as the Seebeck effect (Fig. 5a), while the conversion process of creating a temperature difference upon an applied voltage is the Peltier effect (Fig. 5b).\textsuperscript{92} The working mechanism of the thermoelectric effect is related to the perturbation of charge carriers in equilibrium distribution. When there is a temperature gradient, the charge carriers migrate from high temperature to low temperature, leading to the generation of voltage. The performance of thermoelectric materials is characterized by the dimensionless thermoelectric figure of merit, $ZT$:

$$ZT = \frac{\sigma S^2 T}{k},$$

where $\sigma$ is the electrical conductivity, $S$ the Seebeck coefficient, $T$ the temperature, and $k$ the thermal conductivity.\textsuperscript{93} Based on equation (2), an ideal thermoelectric material should possess a high electrical conductivity, a high Seebeck coefficient and a low thermal conductivity. The optimum carrier concentration for
high thermoelectric performance and thermoelectric power factor ($\sigma S^2$) is illustrated in Fig. 5c.

Besides the well-known thermoelectric materials like Bi$_2$Te$_3$, Sb$_2$Te$_3$, PbTe, etc., emerging 2D nanomaterials with high electrical conductivity or high Seebeck coefficient, such as graphene,\textsuperscript{94-96} TMDCs,\textsuperscript{97,98} and MXenes,\textsuperscript{99,100} are also promising for thermoelectric applications. Interestingly, controlling the alignment of 2D nanomaterials is a great way to enhance the thermoelectric performances. The pivotal concepts of this enhancement are to i) increase ion mobility in aligned carrier pathways for improved electrical conduction, and ii) induce more phonon scattering to suppress thermal conduction or tune the thermal conductivity along the selected directions. For example, Chang et al. investigated the role of alignment in Bi$_2$Te$_3$ 2D nanosheets for thermoelectric applications.\textsuperscript{101} The 2D Bi$_2$Te$_3$ nanosheets with vertical alignment to the SiO$_2$/Si substrate were grown by pulsed laser deposition at 500 °C (Fig. 5d,e). The good alignment contributed to the improved electrical conductivity and Seebeck voltage generation compared to the randomly aligned nanosheets (Fig. 5f). Consequently, an in-plane thermoelectric power factor of 1.35 $\mu$W cm$^{-1}$ K$^{-2}$ was obtained in vertically aligned nanostructures, which was effectively improved compared to that in random conditions ($< 1$ $\mu$W cm$^{-1}$ K$^{-2}$). In another example, Oh et al. achieved significantly improved thermoelectric properties in an aligned MoS$_2$/graphene nanoribbon heterojunction.\textsuperscript{102} The vertical heterojunction was designed to maximize the carrier transport: the carriers can pass back and forth between the graphene and MoS$_2$ nanosheets easily to induce the thermoelectric effect. The as-synthesized nanostructure exhibited an enhanced electrical conductivity of 700 S m$^{-1}$ and a high power factor of 222 $\mu$W m$^{-1}$ K$^{-1}$. In addition, Wu et al. developed regenerated cellulose (RC)/BNNS composite filaments with oriented microstructure using a wet-spinning procedure which will be described later in the review.\textsuperscript{103} With the alignment, the large-sized BNNS were confined among adjacent RC nanofibers at a high filler loading, providing high anisotropy to the filaments (Fig. 5g-h, 5j-k). The aligned RC/BNNS composites displayed extraordinary thermal conduction and could be used in wearable thermoelectric generator (TEG) devices that can promptly transport body heat from skin to surface of the composites. The maximum Seebeck voltage of 84 mV was achieved at an ambient temperature of 5 °C (Fig. 5i). Therefore, the aligned composites can be utilized as wearable heat spreader to improve energy harvesting efficiency, which demonstrate potential in high-performance wearable electronics (Fig. 5i). These exciting examples demonstrate how the orientation of 2D nanomaterials can be leveraged to increase functionalities of thermoelectric devices for robotics, energy harvesting, electronics, among others.

2.3 Electrochemical energy harvesting

An ideal electrochemical energy storage (EES) device should have low cost, long life span, high energy and power density, good recycling stability, and be safe. Two main types of EES devices are batteries and supercapacitors that are composed of two porous electrodes separated by a porous layer, the electrolyte. During charging and discharging, ions, such as lithium, travel back and forth between the cathode and the anode through the electrolyte (Fig. 6a). In supercapacitors, the energy storage is attributed to a double layer capacitance and a surface redox reaction creating a pseudocapacitance, as described in Fig. 6b. Since the discovery of graphene, 2D nanomaterials have become predominant electrode materials in pursuit of high power and energy density for batteries and supercapacitors.\(^{105-107}\) For example, MXenes have a conductive inner transition metal carbide layer that allow fast electron supply to active sites. Meanwhile, a transition metal oxide-like surface is redox active, and 2D morphology and nanoconfined fluid molecules enable fast ion transport.\(^{108-110}\) The MXene electrode structure in supercapacitors is able to deliver up to 210 F g\(^{-1}\) at a scan rate of 10 V s\(^{-1}\) and a volumetric capacitance of \(\sim 1,500\) F cm\(^{-3}\).\(^{111}\) However, 2D nanomaterials used as electrodes tend to aggregate and restack into microparticles, which result in low electrolyte ionic conductivity and high electrode tortuosity and further limit ion transport between the electrode and the electrolyte. The ion transport in electrolytes includes ion migration and ion diffusion. It is related to the intrinsic conductivity of ions and the tortuosity of the porous electrode. The effective diffusivity in the electrolyte is commonly defined as:

\[
D_{\text{eff}} = D \times \frac{\epsilon}{\tau},
\]

where \(D\) is the diffusion coefficient, \(\epsilon\) is the porosity, and \(\tau\) is the tortuosity. An empirical correlation between \(\epsilon\) and \(\tau\) is provided by the Bruggeman-type relationship:

\[
\tau = \frac{\gamma \epsilon^{1-\alpha}}{\alpha}
\]

where \(\alpha\) is the Bruggeman exponent correlated with the porosity, and \(\gamma\) is a scaling factor.\(^{112}\) When the conductive pathways are composed of straight channels that are parallel to the transport direction, \(\tau\) is 1.\(^{113}\) A lower value of tortuosity leads to higher effective ionic diffusivity and ionic conductivity. Therefore, to facilitate ion transport in 2D nanomaterials-based electrodes, designing vertically aligned microstructures is a promising strategy to enhance power and energy density (Fig. 6c).\(^{113}\) Numerous examples in the literature illustrate the benefits of this strategy in batteries and supercapacitors.\(^{114,115}\) The most recent progress in this domain are reviewed in the following paragraph.

Vertically aligned structures composed of 2D nanomaterials including graphite, graphene, lithium metal phosphate, MXene, and transition metal oxide have exhibited outstanding performances and promising commercialization for batteries and supercapacitors. Indeed, vertical alignment of 2D nanosheets enables directional ion transport that can lead to thickness-independent electrochemical performances in thick films.\(^{116-119}\) A recent work demonstrated successful alignment of graphite with superparamagnetic nanoparticles of Fe\(_3\)O\(_4\) driven by magnetic field, which allows cycling at a fast rate of up to 2 C with a specific charge three times higher than the anode with a disordered structure.\(^{120}\) The out-of-plane tortuosity of the graphite aligned perpendicularly to the current collector is reduced by nearly four. In addition to graphite, graphene has attracted much more attention because of its excellent electrical conductivity and ultrahigh surface area. Described by Hao et al., three structures of graphene including vertically (VGA), horizontally (HGA), and randomly (RGA) aligned electrodes were fabricated that showed a tortuosity of 1.25, 4.46, 1.76, respectively.\(^{121}\) High electrode tortuosity induced locally higher current density on the top surface of horizontal alignment and random graphene which resulted in dendritic Li overgrowth on the surface (Fig. 6d,e). On the contrary, lower electrode tortuosity in the vertically aligned graphene enabled homogeneous Li transport and uniform Li deposition across vertically aligned graphene (Fig. 6f).\(^{121}\) Cycling Li on the different anodes in Fig. 6g, the HGA electrode showed a decay of the Coulombic efficiency (CE) of 90% after 24 cycles, whereas the CE of the RGA electrode decreased by 90% after 48 cycles. In turn, the VGA electrode held a stable CE of \(\sim 99.08\%\) after 150 cycles. In the voltage-capacity test, VGA presented lower overpotential (46 mV) than RGA (67.5 mV) and HGA (82 mV) (Fig. 6h), and held a stable overpotential of \(\sim 46\) mV even after 150 cycles (Fig. 6i).\(^{121}\) In another example, an electrode with vertically aligned Fe\(_3\)O\(_4\)/GO exhibited energy density of 724 mA h g\(^{-1}\) at 2 A g\(^{-1}\), which was much higher than that with horizontal alignment.\(^{122}\) Beyond graphene, MXenes also have a large potential for enhanced supercapacitors. Vertically aligned MXenes allow ion transport directly inside the electrode which result in thickness-independent electrochemical performances. An example of vertically aligned titanium carbide (Ti\(_3\)C\(_2\)T\(_x\), MXLLC) was achieved by mechanical shearing.\(^{116}\) The vertically aligned MXLLC exhibited much higher cyclic voltammogram performances than the horizontally aligned film. Furthermore, the Nyquist plots of MXLLC electrodes were nearly vertical at all frequencies, indicating that fast ion diffusion was critical for the independence to the thickness (Fig. 6k). In addition, the rate performance of the MXLLC films declined negligibly when the film thickness was increased from 40 \(\mu\)m to 200 \(\mu\)m (Fig. 6l). Some studies on vertically aligned structures in electrodes for EES are collected in Table 1, which demonstrate the better performance of vertical over horizontally oriented electrodes. These selected examples illustrate how controlling the orientation of 2D nanomaterials enhances the performance of batteries and supercapacitors.

We have seen that controlling the orientation of 2D nanomaterials can enhance the properties and functionalities of sensing and thermoelectric devices, as well as batteries and supercapacitors. These few devices are playing a major role in the development of greener energies, to detect polluting elements or generate energy.

We classify these orientation types into horizontal, vertical, heterogeneous, and arbitrary structures. Overall, some methods lead to one of these orientation types, whereas others can produce several, which is the case for example of magnetically assisted orientation and chemical vapor deposition (CVD). The methods that can achieve versatile orientations by tailoring the fabrication parameters will be discussed as arbitrary structural alignment processes. In this section, we give an overview of the most representative processing methods to achieve the four alignment types mentioned earlier using 2D nanomaterials. The advances of different alignment techniques, pivotal control parameters and typical aligned structures are discussed.

3.1 Horizontal microstructures
A material with good horizontal orientation of 2D nanomaterials shows typically exfoliated, dispersed nanosheets, that are stacked in a highly ordered aligned structure. In turn, this alignment allows a higher concentration of nanosheets and highly compact assembly. Thanks to this horizontal orientation, the anisotropic nanoscopic properties of the 2D nanomaterial can be transferred to the larger structure. For example, the anisotropic orientation can strengthen the macroscopic

| Electrode                  | Orientation method | Electrode thickness | Cycling stability       | Energy power& density | Ref. |
|---------------------------|--------------------|---------------------|-------------------------|-----------------------|------|
| 3D aligned Fe₂O₃/GO       | Freeze-casting     | ~600 µm             | -                       | 724 mA h g⁻¹ @ 2 A g⁻¹| 122  |

material along the aligned direction, while the properties in the perpendicular direction are not affected. The techniques to obtain horizontally aligned structures typically are vacuum-assisted filtration, tape casting, wet spinning, centrifugal casting, direct bottom-up synthesis, hot pressing and self-assembly, and are summarized in Table 2. The mechanisms, characteristics and advantages of these techniques are systematically introduced in this section.

3.1 Vacuum-assisted filtration

Vacuum-assisted filtration (VAF) or vacuum-assisted self-assembly (VASA), is a flexible technique to synthesis well-ordered and free-standing films or papers. It is one of the simplest and most commonly used methods to achieve horizontal alignment for a wide variety of 2D nanomaterials. Fig. 7a1 illustrates the fabrication process using VAF of a film with horizontally ordered layers, starting from a liquid solution containing dispersed nanosheets. This method utilizes vacuum-generated flow to filter the nanosheets from the aqueous or organic dispersion over a filtration membrane. In addition, to obtain a homogeneous dispersion in the final layered nanosheets and increase its mechanical properties, a hydrophilic or hydrophobic polymer can be added into the dispersion. The mechanism of the horizontal alignment via VAF is explained by the densification process during solvent removal. In a typical vacuum filtration process, when the solvent is gradually removed, the well-dispersed nanosheets are brought into close contact, leading to formation of semi-ordered loose aggregates. As the top loose aggregates are exposed to the air-solvent interface, the compression force brings the nanosheets to the perpendicular direction of the flow. The gaps between nanosheets close, resulting in the formation of a compact film. In the end, assisted by VAF, the disordered nanosheets in solution are sequentially aligned parallel to the air-solvent interface (Fig. 7a2-a4). For example, Lin et al. synthesized highly-aligned graphene oxide (GO) papers by using VAF. Thanks to the ultralarge GO nanosheets (average area of 272.2 μm²) with compact stacking and well-aligned microstructures, the GO paper achieved more than 3-fold improvement in electrical conductivity and enhanced mechanical properties including Young's modulus by 320% and tensile strength by 280%. Similarly, Ling et al. reported flexible and free-standing Ti3C2Tx MXene films fabricated by VAF. By tailoring the MXene content in solution, the obtained film thickness can be easily controlled. The as-fabricated Ti3C2Tx films could be used as electrodes in supercapacitors because of the rapid cation intercalation between the well-aligned layers. Moreover, Ding et al. manufactured membranes with horizontally oriented MXene using VAF. Owing to the regular sub-nanometer spacing between aligned MXene layers, the membrane provided fast and precise molecular sieving channels for gas separation with H2 permeability higher than 2200 Barrer and the H2/CO2 selectivity higher than 160. Although VAF method has multiple advantages such as unlimited material selection, simple setup and facile control of film thickness, it also has limitations from the time-consuming procedure and prerequisite of low viscosity for efficient filtration, especially when a polymer is involved.

3.1.2 Tape casting

Tape casting, doctor blading or knife coating, is a well-established method to induce shear-induced alignment and to fabricate thin membranes from a viscous slurry. The membrane thickness can vary from 0.01 to several millimeters, and can be controlled by setting the distance between the doctor blade and the substrate. More importantly, the membrane’s lateral dimension is only limited by the shear apparatus, allowing its utilization in commercial production. In a typical slurry preparation, the 2D nanosheets or ceramic precursors are mixed with solvent, dispersant, binder and plasticizer at a ratio optimized for homogeneity and shear-thinning properties. The procedure is to use the doctor blade to spread out the slurry over a flat substrate (Fig. 7b1). Due to the shear generated by the motion of the doctor blade, the initial random orientation of the 2D nanosheets in slurry is overcome and well-aligned layers are formed. For example, Akbari et al. introduced tape casting as a scale-up method to fabricate highly ordered graphene-based membranes. The top surface morphologies of the film showed good uniformity and continuity (Fig. 7b2). They further investigated the extent of local orientation as the in-plane stacking order in the membranes using polarized light imaging, where a scalar parameter, S, was used to quantify the alignment extent (Fig. 7b3). This scalar parameter is defined by:

\[ S = \frac{1}{2} < 3 \cos^2 \theta - 1 > \]

where \( \theta \) is the angle between mean azimuth and each pixel. When \( S = 1 \), the alignment is perfectly oriented in parallel, while \( S = 0 \) represents the completely random alignment. As a result, the shear-aligned membrane exhibited S values about 0.99. Their results indicate the potential of tape casting to obtain aligned 2D nanomaterials.

3.1.3 Wet spinning

Wet spinning is a mature technology that is industrially viable. It is a solution spinning process, where a thermoplastic polymer is dissolved in a solvent and extruded through a spinneret to form fibers that consolidate as the solvent evaporates. When it comes to 2D nanomaterials, this technique has been utilized to fabricate fibers which contain layer-stacked nanosheets. In a typical synthesis procedure, the nanosheets are well-dispersed in an organic solvent. Then, the macroscopic assembly of fibers is conducted by continuously spinning into the coagulation bath via a spinneret (Fig. 7c1,c2). When the dispersion passes through the spinneret, a unidirectional flow is generated that assembles the nanosheets horizontally along the fiber direction. The as-fabricated fibers exhibit dense and layered microstructure containing nanosheets and polymers, which recalls the brick-and-mortar fashion found in natural nacre (Fig. 7c3,c4). Moreover, it should be noted that the successful alignment of nanosheets is closely related to their liquid crystal self-assembly in the initial colloidal dispersion. The formation of
nematic and lamellar liquid crystals with nanosheet colloids is critical in achieving desired alignment, where the material concentration, size and dispersion should be properly controlled.\textsuperscript{140-142}

### 3.1.4 Centrifugal casting

Compared with the previous mechanical force-assisted methods, centrifugal casting is a time efficient method to assemble 2D nanomaterials into highly aligned and compact films.\textsuperscript{57,143} For example, it can complete the synthesis of 10-μm-thick graphene oxide films within 1 minute, which provides possibility of fast processing for industries.\textsuperscript{57} Moreover, centrifugal casting is scalable and can produce continuous films up to the meter scale. Fig. 7d1 presents the schematic of continuous centrifugal casting process of GO nanosheets. In a typical process, the nanosheets are dispersed in solution which continuously deposits on the inner surface of a hollow tube rotating at speeds up to 2500 r min\textsuperscript{-1}. A temperature of about 80 °C can be applied simultaneously to accelerate the solvent evaporation. After reaching the desired thickness and complete water removal, the homogeneous GO film is obtained (Fig. 7d2). Due to the high-speed rotation of the hollow tube, a strong centrifugal force is induced along the radial direction. Meanwhile, the velocity difference between the casted solution and rotating tube generates shear forces along the tangential directions. These forces bring the nanosheets into a compact and highly ordered configuration (Fig. 7d3).\textsuperscript{57,144,145}

3.1.5 Bottom-up approach

Bottom-up approaches are direct ways to synthesize horizontally aligned 2D nanomaterials. They allow the fabrication of films of controlled sizes, thicknesses and orientation, which make them convenient and scalable routes.\(^\text{15}\) Besides chemical vapor deposition (CVD), other representative chemical methods that can grow oriented 2D nanomaterials from small molecules are hydrothermal synthesis and gelation growth.\(^\text{15,147-152}\) For example, the hydrothermal or solvothermal synthesis methods are classical wet-chemical routes for nanomaterials, especially the inorganic ones.\(^\text{153,154}\) They are conducted in a sealed vessel, where the reaction medium is water for hydrothermal and an organic solvent for solvothermal reaction. The principle of the synthesis is to heat the reaction medium above the boiling temperature of the solvent, to generate high pressure which leads to the reaction and growth of nanocrystals. By using a hydrothermal method, Xu et al. synthesized horizontally aligned 2D hybrid sheets of \(V_2O_5\) and reduced graphene oxide (rGO/V\(_2\)O\(_5\)) (Fig. 8a1), which can be utilized as cathodes for lithium-ion batteries.\(^\text{155}\) As shown in Fig. 8a2, the 2D hybrid sheets exhibited a wrinkled surface which increased the accessible surface area for ion interaction. In addition, the cross-sectional SEM image revealed well-defined horizontally oriented layers made of 30 nm-thick nanosheets (Fig. 8a3).

Another typical wet-chemical strategy for directional 2D nanomaterial assembly is gelation growth.\(^\text{151,152}\) It is a simple and straightforward way to assemble macroscopic structures from nanosheets. For example, Yang et al. reported the ordered gelation of graphene hydrogel films from chemically converted graphene in water without the need for additional gelators.\(^\text{156,157}\) Later, Maiti et al. demonstrated the successful fabrication of reduced graphene oxide films in \(\mu\)m-thick hydrogels with porous and planarly aligned microstructures.\(^\text{158}\) To obtain this structure, Zn foils were immersed in a mildly acidic GO dispersion to induce the spontaneous growth of graphene hydrogels on the Zn surface (Fig. 8b1). The mechanism of this spontaneous interfacial gelation can be explained by the reduction process as shown in Fig. 8b2. Because of the lower reduction potential of Zn, there is continuous electron transfer from the Zn metal surface to the GO. As a result, ionized Zn\(^{2+}\) tightly attach to the negatively charged GO nanosheets, leading to layer-by-layer interfacial stacking at the basal planes (Fig. 8b3, b4). Generally, the gelation growth thickness is controlled by the immersion time: a 78-\(\mu\)m-thick gel film can be typically obtained within one hour. At the same time, lateral dimension of the graphene film is determined by the substrate, rendering the procedure scalable.

3.1.6 Hot-pressing

![Figure 8](image_url)

Hot-pressing, which consists in simultaneously applying heat and pressure, is a popular fabrication method to assemble nanomaterials when high relative density is required. Under the uniaxial pressure, planarly oriented microstructure can be formed from pre-stacked nanosheets. Or in other cases, self-aligned texture can be formed during sintering due to the uneven stress distribution around nanosheets. Using this method, Liu et al. fabricated aligned graphene/polycarbonate composites with multiple parallel layers. For planar stacking, each layer thickness was exponentially scaled with successive stacking and folding in quadrant, and the hot-pressing could further improve the interlayer integration. After repeating the process, multiple-layered graphene composites were obtained, presenting closely spaced and horizontally aligned layers. As a result, the elastic modulus and strength were significantly enhanced at exceptionally low volume fractions of only 0.082%. Other than pre-stacking and compressing, the 2D nanomaterials can be alternatively assembled into complex precursor such as granular particles, where the nanosheets are aligned around the sphere, before conducting hot-pressing. Zhang et al. reported thermally conductive but electrical insulating segregated double network in graphene/h-BN-based composites via hot-pressing. Further hot compressing treatment into thinner sheets can improve the intrinsic filler orientation. Additionally, the hot-pressing synthesis procedure is scalable, allowing fabrication of dense product with controllable thickness.

3.1.7 Langmuir-Blodgett (LB) assembly

The Langmuir-Blodgett (LB) method is a classical interfacial assembly strategy that operates at the liquid-air interface. Typically, the molecules or nanosheets are initially dispersed in a water-immiscible volatile organic solvent. After the solvent has evaporated, a water-supported thin layer is formed, which can be later transferred to a substrate and compressed. When it comes to controlled horizontal alignment of 2D nanosheets, the Langmuir-Blodgett (LB) method has been further developed by tuning the dewetting instability of the wet monolayer upon transferring, which involves the wet transition from complete to partial wetting. Consequently, the alignment and patterning design of 2D nanomaterials can be accessible without additional template. Kim et al. investigated the edge-to-edge interactions between neighbouring graphene oxide sheets via LB assembly. In this case, the water surface was utilized as an ideal platform to assemble the 2D nanosheets. To improve the spread capability of nanosheets by LB methods, Nie et al. developed a general method by combining it with electrospray. Benefiting from the reduced volume of the aerosolized droplets, the diminished droplets are depleted rapidly in the initial spreading and leave all the nanoparticles on the water surface, leading to efficient LB assembly as shown in Fig. 9b2.

Table 2 Processing techniques for horizontal alignment of 2D nanomaterials

| Method                  | Alignment principle                                                                 | Achieved structure                                | Advantages                                              | Limitations                                                                 | Ref.            |
|-------------------------|---------------------------------------------------------------------------------------|-----------------------------------------------------|---------------------------------------------------------|-----------------------------------------------------------------------------|-----------------|
| Vacuum-assisted filtration | Vacuum filtration of colloidal solution to compress the 2D nanosheets horizontally | Film, highly ordered, free-standing layered structure | Wide material selection, inexpensive, simple setup     | Time-consuming process, requires low viscosity in colloidal solution         | 129-134,146,172,173 |
| Tape casting            | Apply horizontal shear force on a viscous solution using a doctor blade               | Film, highly ordered, layered structure              | Scalable, industrially adaptable                       | Slow processing                                                            | 137,138,174,175  |
| Wet spinning            | Extrude and spin a self-assembled colloidal dispersion through a spinneret in a solution bath | Fiber, layered structure                            | Industrially adaptable, no thermal degradation         | Slow processing requires volatile organic solvents                        | 139,140,142,176  |
| Centrifugal casting     | Cast the 2D nanosheets dispersion on the inner surface of a rotating hollow tube to align them using centrifugal force | Film, highly aligned, compact layered structure      | Wide material diversity, high efficiency, scalable synthesis | Requires specific equipment, with proper inside diameter for efficient centrifuge | 57,144,145       |
| Hydrothermal            | Heat an aqueous or organic medium above boiling point to induce pressure rise and chemical reaction | Nanosheets/film, well-defined aligned layers         | High quality nanocrystals, high yield, low cost        | Requires specific autoclaves, safety issue during reaction                  | 153-155         |
| Gelation                | Nanosheet hydrogel growth at solid-liquid interface by an electrochemical reaction | Film, porous layered structure                       | Simple setup, scalable, controllability of gel structures | Porous morphology, time-consuming process                                  | 151,156-158     |
| Hot-pressing            | Densification process using uniaxial pressure and temperature to simultaneously align and sinter | Film/bulk, closely-packed structure                  | Compact microstructure, improved mechanical properties | Requires specific equipment and operation, limited efficiency              | 159,163,164,177  |
| Langmuir-Blodgett (LB) assembly | Spread 2D nanosheets at liquid-air interface which align due to capillary forces. | Thin monolayers films                                | Simple operation, accurate thickness control           | Limited resistivity to high temperature, slow deposition                   | 168,169,171,178,179 |

3.2 Vertical microstructures

The anisotropic property of 2D nanomaterials is one of the most critical features to achieve unique functionalities. When they are aligned vertically, the 2D nanosheets can provide more reaction sites from the exposed edges as compared to when they are horizontally aligned. Also, the increased surface area resulting from vertical alignment in forest-like configuration can for example lead to more efficient conduction pathways. In this section, we review several representative strategies to achieve the vertical alignment of 2D nanomaterials. The typical processing, achieved structures, advantages and limitations of the techniques are tabulated in Table 3. Some universal techniques are capable of conducting diverse aligned patterns including horizontal and vertical structures and will be tackled in the arbitrary aligned section.
3.2.1 Shear force

Achieving vertically alignment of 2D nanomaterials is considered more difficult than horizontal alignment since gravitational force needs to be overcome. Shear resulting from flow-induced fluctuations in smectic or lamellar self-assembled colloidal phases, is one effective route. This shear-induced orientation depends on the torque that is generated perpendicularly to the shear direction. Tape casting is a typical technique to shear. Assisted by tape casting, highly-ordered horizontal structures have obtained as mentioned above (Fig. 7b). Nevertheless, tape casting can also lead vertical alignment of 2D nanosheets under controlled conditions (Fig. 10a1). When 2D nanosheets are well-dispersed in aqueous solution, long-range oriented mesophases spontaneously form as the discotic liquid crystal phases where the nanosheets are aligned parallel to each other. Under the external mechanical shear, a vertical torque arising from the flow-induced fluctuation is generated, which orients the aligned nanosheets in the mesophases, vertically (Fig. 10a2,a3). The applied shear rate for vertical orientation should be adjusted according to the particle size, with larger particles requiring a lower shear rate. Furthermore, extrusion is another method to induce shear. As one of the most commonly used processing techniques in plastic industry, it is also suitable for orienting 2D nanomaterials having high anisotropy. The typical extrusion process is illustrated in Fig. 10b1. The critical control parameters to achieve good distribution and orientation of 2D nanosheets include a relatively low processing temperature, suitable draw ratios (the ratio between extrudate pulling velocity and average velocity in extrusion die), sufficiently high local shear rates and shear stresses inside the die for orientation. After extrusion, cutting along the transverse section is required to reveal the vertically aligned nanoflakes (Fig. 10b2). By providing a biaxial stress field by combining rotation and extrusion, the 2D nanoflakes could be further assembled into perpendicular alignment to radial direction (Fig. 10c1-c3).

3.2.2 Laser irradiation
Laser irradiation is a newly developed technique to process and orient 2D nanomaterials. Thanks to recent development of a diverse range of lasers, laser irradiation as a method to process nanomaterials is blooming. Different from most conventional material processing techniques, laser irradiation brings rapid heat and localized high energy to materials, allowing precise control over the material microstructures. Park et al. reported the fabrication method of L-shaped graphene nanostructures with vertical alignment and reduced defect level through laser irradiation. Fig. 11 presents the fabrication process of laser-induced L-shaped graphene nanostructures. Initially, a horizontally aligned graphene oxide (GO) film was prepared by filtration. Then, as the laser irradiated the surface of the horizontally stacked GO film, compression stresses generated because of thermal expansion of individual GO nanosheets. As a result, the GO nanosheets were locally re-aligned in vertical direction. Also, the high energy density from CO2 lasers could even heal the defects within the graphene nanosheets by removing the oxygen-containing functional groups. The as-fabricated L-shaped graphene nanoarchitectures exhibited high hydrophobicity, excellent electron transport and thermal conduction due to the localized vertical orientation and lower defect level.

3.2.3 Hydrothermal and solvothermal synthesis

The hydrothermal and solvothermal synthesis strategies introduced in section 3.1.5 to produce horizontal layers (Fig. 8a) can also create vertically aligned nanosheets. Through hydrothermal reaction, vertically aligned nanosheets have been grown on various substrates under well-controlled growth parameters, and are applicable to diverse material types and geometries such as nanowires, nanospheres, nanosheets, and nanoribbons. Generally, the morphology of the grown nanostructures can be tuned by controlling the template seed growth, reaction temperature, pH and by adding surfactants. Fig. 12a1 displays a typical solvothermal synthesis procedure for vertically oriented VO2(B) nanobelts. Before solvothermal growth, a thin layer of vertically oriented graphene was grown on the flat substrate by plasma enhanced CVD, which improved the vertical growth of the nanobelts into a forest structure with enhanced densification. Later, the precursor slurry was loaded on the graphene coated substrate in an autoclave, in which the densely packed nanostructure self-assembled with vertical orientation as shown in Fig. 12a2 and 12a3. Similarly, vertically alignment of α-MoO3 nano-blades was achieved by hydrothermal method (Fig. 12b1). The obtained nano-blades were arranged in rows and bundles, showing a flower-like structure. The individual nano-blades were of 10 to 50 nm-width without stack onto each other (Fig. 12b2,b3).

3.2.4 Templated growth

Synthesis of vertically aligned 2D nanosheets can also be implemented by the self-assembly of sacrificial particles called templates. Typically, the nanostructures fabricated by template induced self-assembly exhibit highly-interconnected nanostructures, strong interface adhesion and good structural robustness, etc. For example, Zhu et al. investigated a general salt-templating method that led to vertically oriented graphitic carbon nanosheets. Fig. 12c1 presents the schematic illustration of the salt-templating process. In short, the precursor was mixed with the ZnCl2 and KCl salt mixture before being coated onto a nickel foam substrate. After heat treatment and template removal, the vertically aligned and highly-interconnected nanosheets were obtained (Fig. 12c2,c3). In this case, the formation of vertical orientation of the 2D nanosheets could be attributed to two reasons. One is the nickel induced dissolution and crystallization of carbon on the surface of the substrate, leading to the directional growth of graphitic carbon distal to the surface. The other reason is that the salt mixture acts as a porogen and helps in forming separated flat structures.
In another example, Li et al. reported templated growth of vertically aligned 2D metal-organic framework (MOF) nanosheets (Fig. 12d1-d3). To achieve the nanocrystal orientation, a layer of horizontally aligned 1D halloysite nanotubes was deposited as the nucleation sites for 2D MOF nanosheets. This pre-fabricated layer also plays a role in guiding the vertical growth of nanosheets.
Table 3 Processing techniques for vertical alignment of 2D nanomaterials

| Method                  | Alignment technique                                      | Achieved structure                  | Advantage                          | Limitation                     | Ref.          |
|-------------------------|---------------------------------------------------------|-------------------------------------|------------------------------------|---------------------------------|--------------|
| Tape casting            | Induce vertically oriented torque by horizontally shearing with a blade on a solution containing liquid-crystalline nanosheets | Film, vertically packed nanosheets   | Scalable, nearly thickness-independent | Slow processing               | 116,180,182,185 |
| Extrusion               | Align 2D nanoparticles along the extrusion direction through a die and cut perpendicularly to this die | Tube, vertically oriented nanosheets | Flexible alignment direction       | Requires specific equipment and post processing (cutting) | 119,183 |
| Laser irradiation       | Irradiate high energy laser on the surface of a nanosheet film to induce local compression forces | L-shaped nanostructures in thin film | One-step process, local control enabling patterning possibility, reduces nanosheet defects | Requires equipment for laser generation | 186 |
| Hydrothermal/Solvothermal synthesis | Bottom-up nanostructure growth on substrate in solution | Film, direct vertical alignment, densely packed nanostructure | Versatile and cheap, direct growth of nanostructures, low reaction temperature | Requires autoclave equipment and proper safe operation | 192,200,202 |
| Templated growth        | Template induced nanostructure crystallization and growth on pre-fabricated supports | Film, densely packed nanostructure   | Tunable particle size, highly-interconnected nanostructures | Requires pre-fabricated templates and precise control of template growth | 58,201 |

3.3 Heterogeneous microstructures

Beyond purely horizontal or vertical alignment, the creation of more complex microstructures with ordered 2D nanomaterials can also generate novel functionalities. The heterogeneous architectures are typically beneficial for enhancing interfacial interactions of ion diffusion by increasing the density of reaction sites, which may facilitate applications such as catalysis, energy storage and so on. In this section, we review several emerging approaches used to fabricate heterogeneous microstructures as summarized in Table 4. By using different synthesis technologies, diverse periodic textures and microstructures can be effectively tuned.

3.3.1 Crumpling

2D nanomaterials have a large surface area and tunable surface functionalities. They are much easier to bend or fold than stretch in planar direction, leading to morphological surface instabilities.\(^{203,204}\) This mechanical instability has been further utilized to create 3D crumpled architectures with the assistance of external stimuli. Crumpled graphene films, as an example, are extensively studied for energy storage, electronics, biomedicine, etc., where the crumpling degree is pivotal in determining their performances.\(^{205,206}\) To crumple a graphene film, this film is first adhered on a pre-stretched elastomeric polymer substrate or any other substrate able to shrink. When the substrate relaxes, it shrinks, inducing compression in the graphene layer that crumples due to its high stiffness (Fig. 13a1).\(^{59,207-209}\) Furthermore, the substrate shrinkage can be controlled to be isotropic or anisotropic. For isotropic shrinkage, the sample is simply annealed without mechanical stress, showing a flower-like crumpled morphology (Fig. 13a2). As for anisotropic, uniaxial and hierarchical crumpling, the relaxation of the substrate is conducted by anchoring one of its side during the shrinkage (Fig. 13a3,a4).\(^{59}\) The crumpled patterns are typically in sub-micro scale, which are applicable for various applications such as electrochemical catalysis, strain sensor and stretchable conductor.\(^{210,211}\) The crumpling method could be more suitable for synthesizing small sample sizes rather than scalable products to precisely control the shrinkage of substrate.

3.3.2 Scrolling

Scrolling is a simple way to assemble 2D nanomaterials into fibers with heterogeneous structure, which typically shows a
spiral cross section. It provides broad material selections without specific requirements of the composition, chemical bonding or nanomaterial dimension. During scrolling, a planar film containing ordered nanosheets is rolled into a cylinder. The dimensions and intrinsic microstructure of the cylinder can be easily controlled by varying the initial film parameters, such as thickness and orientation.\(^\text{118,163}\) \textbf{Fig. 13b1} provides an example of transverse shear scrolling method. Liu et al. demonstrated the feasibility of this method for fabricating closely packed spiral microstructures in graphene-based nanocomposites (\textbf{Fig. 13b2} and \textbf{13b3}).\(^\text{163}\) The scrolled graphene nanocomposites with heterogeneous structure exhibited anisotropic electrical conduction along the graphene planar axis with electrical conductivity about 4.5 \(\text{S cm}^{-1}\) at a low volume fraction of about 0.185\%, and the transparency was maintained at the same time. Similarly, Chen et al. reported the fabrication of tightly packed and interconnected BN nanosheets composites using scrolling.\(^\text{212}\) These nanocomposites exhibited enhanced through-plane thermal conductivity of 1.94 \(\text{W m} \text{K}^{-1}\) with 15.6 \(\text{vol}\%\) BN nanosheets, which are beneficial for thermal management applications. The heterogeneous structures of 2D nanomaterials synthesized by scrolling are typically fibers in micro or millimeter scale, which are still challenging for industrial fabrication.

3.3.3 Layer-by-layer (LBL) assembly

Layer-by-layer (LBL) assembly is one of the most extensively used methods for synthesizing nanocomposites with heterogeneous compositions and structures at high filler loadings. It consists in assembling individual layers of nanoparticles in a sequential manner, therefore allowing for the fabrication of building heterogeneous structures composed of different components. LBL assembly is thus a versatile approach to combine individual layers of various morphologies or different material type, and where the film thickness can be precisely controlled.\(^\text{213-215}\) In practice, the LBL assembly is realized using dipping, spinning or spraying as shown in \textbf{Fig. 14a1-a3}. In a typical LBL dipping assembly procedure, a substrate is sequentially immersed into the colloidal solutions containing the nanosheets. The heterogeneous film with multilayer structure can be formed by repeating the dipping process.\(^\text{200}\) The formation of layered structure with high ordering is closely related to the strong interactions between individual components, such as electrostatic force, covalent bonding, hydrophobic interaction and so on.\(^\text{129,213}\) To guarantee high LBL packing, the deposited material components should be selected to bond together. This can be improved by introducing surface modifications such as functional groups or surfactants. For example, Lee et al. utilized spin coating LBL method to assemble positively charged rGO and negatively charged rGO as one bilayer. A multilayer structure with 10 bilayers was obtained by repeating the procedures (\textbf{Fig. 14a4}).\(^\text{210}\) The size and thickness of the fabricated structures are set by the substrate dimension and repeat times, respectively, which provide possibility for scale-up applications.

3.3.4 Freeze-drying assisted self-assembly

2D nanomaterials with high aspect ratios can be self-assembled into aligned domains when they are in the liquid crystal form.
Liquid crystals (LCs) are particles in the intermediate state between amorphous liquid and crystalline solid. LCs therefore exhibit mobility and self-assembled ordering under competing driving forces from packing and orientation entropies. LC size, concentration, repulsion and solvent viscosity greatly influence their self-assembling behavior. Furthermore, with the assistance of freeze-drying, which provides rapid growth of ice crystals, the self-assembly of 2D nanosheets from dilute LC suspension can be induced by concentrating the LCs between the crystals. As an example, Yao et al. organized GO nanosheets into LCs with high heterogeneous orientations by increasing the pH value of their dispersion with potassium hydroxide (KOH) (Fig. 14b1). The self-assembled nanosheets exhibited inherently interconnected microstructure. In strong alkaline base such as KOH, the enhanced electrostatic repulsion between GO sheets could be increased, leading to higher fluidity and a highly ordered texture. After hydrothermal reduction of GO LCs and subsequent freeze-drying, a spiral microstructure with better aligned nanosheets were obtained mainly due to the alignment of GO nanosheets in LCs along the inner surface of container (Fig. 14b2, b3). More examples of self-assembled macroscopic orientation of liquid crystals can be found in Fig. 14c and 14d. Overall, freeze-drying assisted self-assembly method involves simple procedures but may be limited in scalability and material diversity because it requires more strict control of nanomaterial selection and operation with suitable size, aspect ratio, material chemistry and fabrication parameters to achieve desirable assembled microstructure.
### 3.4 Arbitrary microstructures

The orientation and distribution of 2D nanomaterials are key factors that determine the macroscopic performances of films and bulk materials made from them due to their anisotropic properties. These performances include mechanical, electrical, thermal, optical properties and so on. Therefore, methods capable of controlling the microstructure in predesigned orientation patterns are highly desirable. The methods that can create arbitrary microstructures are therefore reviewed in this section, and their representative features are summarized in Table 5. Through these technologies, a variety of aligned patterns can be achieved within a single method, allowing materials with highly tunable local orientation and versatile properties.

#### 3.4.1 Magnetic field assisted orientation

Magnetic field is a powerful tool in precisely and remotely controlling the local orientation of anisotropic materials, including 2D nanomaterials.\(^6\) This approach utilizes external magnetic fields to align particles with anisotropic magnetic susceptibility suspended in a liquid matrix.\(^22\) As 2D nanomaterials are often diamagnetic, extremely high magnetic fields are usually required for alignment.\(^22\) To solve this problem, superparamagnetic nanoparticles such as iron oxide nanoparticles can be coated on the surface of the nanosheets to make them more responsive to magnetic fields.\(^22\) During magnetic alignment in suspension, the dynamics of particles is synergically controlled by torques generated from the magnetic, gravitational, and viscous forces. Several key factors can influence the particle orientation, including the particle geometry, magnetic field strength and gradient, particle concentration and fluid viscosity. After positioning the particles, the fluid is consolidated to fix the orientation, which can be achieved by solvent evaporation, light or temperature-controlled curing, depending on the solvent type.\(^42\) To create complex local assemblies, virtual magnetic molds can be used.\(^31\) These molds consists in placing a ferromagnetic material above a magnet. The ferromagnetic material then becomes magnetized and attract the particles locally. Combined with a dynamic magnetic field instead of a static field, 2D particle orientation at set directions with local particle concentration can be achieved. Fig. 15a shows the alignment processing of gelatin-based composites containing magnetically responsive reduced graphene oxide (m-rGO) flakes.\(^6\) By controlling the magnet placement and by using a virtual magnetic mold made of Co or Ni template, both orientation and spatial distribution of m-rGO flakes can be effectively tailored within the composites. By choosing predefined meshes as the template, the m-rGO flakes could be assembled into hierarchical double-percolating networks (Fig. 15b), enabling both optical transparency and electrical conductivity at reduced percolation threshold of 0.65 to 0.85 vol% of rGO. In addition, Lin et al. demonstrated the magnetic response and alignment of graphene flakes, where the displayed patterns of graphene suspension were induced by different shapes and configurations of magnets (Fig. 15c-f).\(^22\) Later, when the static magnetic field was switched to a rotating magnetic field in the x-y direction (Fig. 15g), the graphene nanosheets were aligned in planar direction, exhibiting much higher birefringence and anisotropic absorption/transmission capabilities than those without magnetic field or with static magnetic field (Fig. 15h-j). Overall, magnetic orientation of 2D nanomaterials is applicable to wide range of material chemistry and the alignment angle can be easily programmed by changing the direction of magnetic field, while the sample dimension is usually limited by the magnet size.

| Method                        | Alignment technique                                                                 | Achieved structure                              | Advantage                                                                 | Limitation                                                                 | Ref.                   |
|-------------------------------|-------------------------------------------------------------------------------------|-------------------------------------------------|---------------------------------------------------------------------------|---------------------------------------------------------------------------|------------------------|
| Crumpling                     | Induce compressive stresses in a film of horizontally aligned nanosheets.            | Crumpled film                                   | Facile method, controllable crumpled patterns                             | Limited scale (e.g., micrometer-scale), time consuming                    | 59,207-209             |
| Scrolling                     | Scroll layered nanosheets into fibers                                              | Fiber, spiral structure                         | Simple procedure, high packing density, unlimited material type           | Requires precise operation                                                | 118,163,212            |
| Layer-by-layer assembly       | Sequential deposition of individual layers into a multilayer structure             | Film, multiple layers                           | Simple procedure, low cost, precise film thickness control                | Requires strong interaction between individual layers, slow fabrication speed | 129,213,216,219        |
| Freeze-drying assisted self-assembly | Self-assembly of liquid crystals under proper conditions                   | Film/Bulk                                          | Simple procedure, inherently interconnected microstructure               | Requires precise control of liquid crystal alignment condition         | 205,218,220            |

3.4.2 Electric field assisted orientation

Similar to the magnetic fields, electric fields can serve as the external driving force to align anisotropic particles in programmable directions. Electric field induced alignment is compatible with dielectric materials or electrically conductive fillers, such as graphene nanoplatelets, graphite, BNNS or fluorohectorite nanosheets, which are typically mixed in a low viscosity, organic medium.229,230 These 2D nanomaterials can respond to the electric field and form oriented patterns because they can be polarized by the external field and acquire a dipole moment. During the electrical alignment, a high-frequency alternating current (AC) electric field is commonly used to orient the 2D nanomaterials and also avoid the electrophoresis of nanosheets and the electrolysis of the medium.231,232 Under this alternating AC electric field, any solid inclusion suspended in a dielectric liquid will be polarized and acquire a dipole moment because of the mismatch in dielectric properties and electrical conductivity between the particles and their surrounding matrix. For 2D nanomaterials with considerable anisotropy, the polarization moment generally develops along their basal plane. When the polarization moment is not aligned along the electric field, a torque is

created that rotates the particles and align their basal plane along the electric field direction to reach an equilibrium state. Once aligned, the polarized nanosheets can attract each other due to opposite surface charges, leading to an end-to-end chain configuration (Fig. 16a-d). Theoretically, similar to magnetic alignment, the electric field induced alignment method can achieve arbitrary orientation directions, simply by tuning the electric field. For example, complex and intricate ordered patterns can be fabricated by sequential electric field induced orientation and photolithographic consolidation (Fig. 16e-j). Moreover, the electric field induced alignment of 2D nanomaterials should be differentiated from the electrophoretic deposition (EPD) for materials like rGO or MXene, in which the charged particles cannot be polarized but will move towards to the electrode of opposite polarity and deposit on the surface.

3.4.3 Freeze casting

Freeze casting, or also known as ice templating, is a well-established technique that is utilized to fabricate arbitrary oriented patterns, such as horizontal, vertical, gradient, layered, honeycomb, and radial structures. It is a versatile technique applicable to diverse material types not limited to 2D nanosheets. The four processing steps of a typical freeze casting procedure are liquid suspension preparation, solidification, sublimation and post-treatment as shown in Fig. 17a. Dispersant, plasticizer and binder are commonly added in the initial liquid suspension to ensure uniform dispersion of the 2D nanoparticles in the liquid medium. The microstructure is determined by the formation of ice dendrite during the solidification stage. After sublimation of the ice, the subsequent post-treatment, such as sintering densification, thermal reduction or pyrolysis, will transform the material into a porous scaffold. The desirable oriented patterns are thus set during the solidification, when the suspended particles are rejected by the moving solidification front, concentrated and entrapped between the ice crystals. Fig. 17b illustrates the freezing front progression at different velocities, where \( v \) is the particle freezing front velocity, and \( v_{cr} \) is the ice critical freezing front velocity. At very low solidification velocity (\( v < v_{cr} \)), the particles are not rejected by the ice front, so that no pattern forms. At \( v < v_{cr} \), the particles are generally rejected and assembled in a lamellar microstructure. And at \( v \geq v_{cr} \), some particles could be further entrapped, leading to bridges between the lamellar structure. If the freezing rate is too rapid (\( v \gg v_{cr} \)), the particles are instead encapsulated within the ice front. Moreover,
different thermal gradients can be introduced to control the growth direction of the ice dendrites.\textsuperscript{241} For example, Bai et al. compared the scaffolds prepared by unidirectional freeze casting and bidirectional freeze casting techniques using hydroxyapatite (HA).\textsuperscript{242} For unidirectional freeze casting, a single vertical temperature gradient was applied, leading to the simultaneous crystal nucleation over the substrate (Fig. 17c). The obtained scaffold showed multiple domains with various orientations in the planar direction (Fig. 17d). For bidirectional freeze casting, a PDMS wedge was placed between the slurry and the cold substrate, leading to the combination of both horizontal and vertical temperature gradients (Fig. 17e). The as-fabricated scaffold showed a well-aligned monodomain lamellar structure along the dual temperature gradients (Fig. 17f). Moreover, Shao et al. demonstrated the fabrication of 3D hierarchical porous graphene films by using freeze casting.\textsuperscript{243} The graphene oxide (GO) as a precursor was partially reduced to micro-gels and filtered before freeze casting. Ideally, continuous ice crystals are formed and the GO nanosheets are rejected from the solidification front to get highly porous microstructure. The obtained 3D porous GO films exhibited a high electrical conductivity of 1905 S m\textsuperscript{-1} and good mechanical stability with only 9% decay of discharge capacitance after 500 bending cycles. Bian et al. reported a direct freeze casting route for the fabrication of ultralight Ti$_3$C$_2$-MXene aerogels with density lower than 10 mg cm\textsuperscript{-3}.\textsuperscript{244} The MXene aerogels showed a specific shielding effectiveness of 9904 dB cm\textsuperscript{-3}g\textsuperscript{-1} with a reflection lower than 1 dB, which can be useful for electromagnetic interference (EMI) shielding applications. Additionally, more freeze casting control strategies such as radial freeze casting or external field assisted freeze casting have been implemented, providing controllable assembly methods for 2D material applications.\textsuperscript{36,245,246}
3.4.4 Chemical Vapor Deposition (CVD)

Chemical Vapor Deposition (CVD) is a widely used technique that involves gaseous material reaction and subsequent solid deposition on a substrate. As a versatile bottom-up growth method to synthesize oriented 2D nanomaterials, the obtained material morphology and alignment can be tuned by controlling the growth parameters such as selective source materials, temperature, pressure, gas flow rate and so on.\(^\text{247}\) The CVD fabrication method is classified as an arbitrary alignment technique here because the 2D nanomaterials can be formed into several types of alignment, typically including horizontal, vertical and heterogeneous alignment structures.\(^\text{55,248-253}\) The alignment of the grown 2D nanomaterials such as TMDCs can be tuned upon different CVD growth conditions. Dumcenco et al. reported the morphology changes of MoS\(_2\) by tuning sample temperature.\(^\text{254}\) When the gas injection temperature gradually decreased from 700 °C to 600 °C, the MoS\(_2\) domains went through the vertically aligned multilayers to reduced longitudinal length, and finally changed into the horizontally aligned monolayers. Cho and co-workers fabricated MoS\(_2\) films with different alignment directions by rapid sulfurization of CVD (Fig. 18a-d).\(^\text{55}\) The growth direction of the TMDCs films could be controlled by the thickness of pre-deposited metal seed layer.\(^\text{55,248,251}\) Horizontal (Fig. 18e), mixture of horizontal and vertical (Fig. 18f), to vertical alignment (Fig. 18g) were achieved with increasing seed layer thickness. Later, Kumar et al. investigated the horizontal to vertical growth of MoS\(_2\) films by tailoring the supersaturation ratio of the S:MoO\(_3\) precursors.\(^\text{249}\) These various aligned structures obtained from direct growth by CVD indicate the possibility to better control the 2D nanomaterials. At the same time, CVD is a scalable method to fabricate diverse nanomaterials with high quality, which requires precise control over the grow parameters.

In summary, the alignment of 2D nanomaterials can be well controlled through various processing methods involving self-driven or directed assembly. Based on the desired material and target orientation patterns required for a specific property and application, people can select the appropriate fabrication techniques. Furthermore, the selection of the most adequate fabrication process to achieve a target microstructure should also consider (i) the available material quantity and form. For example, all processes except CVD and hydrothermal and gelation require a well-disperse, stable dispersion of 2D nanosheets in a medium; (ii) the intended final relative density. For example, porous structures can easily be formed using freeze-casting, salt templating, or gel casting, whereas hot pressing or vacuum filtration, among others, lead to dense films; (iii) the intended properties and chemistry of the 2D nanomaterials. Indeed, the processes requiring chemical reactions or intrinsic properties like anisotropic electric response are chemically dependent, whereas others are mostly based on the physical properties of the nanosheets such as their dimensions, like magnetic fields, freeze-casting, filtration, etc. Furthermore, the methods reviewed here are representative of the most commonly used methods and have numerous variations in the literature. Although some can produce bulk samples, couple several materials or have heterogenous alignment patterns, one common limitation of these methods is their inability so far, to decouple the final material shape with the local microstructure. This limits the potential for design and the fabrication of complex structures. Without design flexibility, giving a bright future for energy devices and others with boosted performances.

### 4. 2D nanomaterials alignment supported by 3D printing

Substantial efforts have been made to develop various processing techniques to achieve controlled orientations of 2D nanomaterials. One recent and extremely important and groundbreaking technique is 3D printing, which offers unlimited design flexibility. 3D printing is a process that builds up an object in layers, with each new layer adhering to the one below. For 2D nanomaterials, 3D printing can provide a localized scaffold density, with tunable microstructures. This made 3D printing a suitable method of producing 2D nanomaterials with appropriate densities, which can be highly dependent on the local microstructure. The following section outlines how 3D printing can support the fabrication of complex structures. It should be noted that 3D printing requires precise local control of scaffold density, resulting in high density of solidification front control. This is limited by magnet size and sample dimension is limited by magnet size.

### Table 5 Processing techniques for arbitrary orientation

| Method         | Alignment technique                                                                 | Achieved structure      | Advantage                                                                 | Limitation                                                                 | Ref.             |
|----------------|--------------------------------------------------------------------------------------|-------------------------|--------------------------------------------------------------------------|---------------------------------------------------------------------------|-----------------|
| Magnetic field | Apply external magnetic fields to align 2D nanosheets having anisotropic magnetic susceptibility | Bulk/Film, highly tunable localized orientation | Low cost, applicable to wide material type, any orientation angle          | Limited scaffold density, sample dimension is limited by magnet size       | 42,60,222,225   |
| Electric field | Apply external electric field to align 2D nanosheets having anisotropic electric susceptibility | Bulk/Film, tunable control of local particle alignment | Low cost, scalable, facile to tune electric field distribution            | Requires dielectric polarization and requires multi-step process for complex patterns | 231-233         |
| Freeze casting | Control nucleation and directional growth of ice crystals under temperature gradients to push the 2D nanosheets into patterns | Bulk/Film, porous scaffolds, well-oriented patterns | Applicable to wide range of materials, scalable, tunable microstructures of freeze-cast scaffolds | Limited scaffold density, requires precise control of solidification front growth | 49,240-242,255  |
| CVD            | Gaseous chemical reaction and solid deposition on substrate surface                   | Film, tunable aligned structure through growth conditions | Scalable, high material quality                                          | Limited layer thickness, cannot change orientation angle freely            | 55,247-249,251,252 |

In summary, the alignment of 2D nanomaterials can be well controlled through various processing methods involving self-driven or directed assembly. Based on the desired material and target orientation patterns required for a specific property and application, people can select the appropriate fabrication techniques. Furthermore, the selection of the most adequate fabrication process to achieve a target microstructure should also consider (i) the available material quantity and form. For example, all processes except CVD and hydrothermal and gelation require a well-disperse, stable dispersion of 2D nanosheets in a medium; (ii) the intended final relative density. For example, porous structures can easily be formed using freeze-casting, salt templating, or gel casting, whereas hot pressing or vacuum filtration, among others, lead to dense films; (iii) the intended properties and chemistry of the 2D nanomaterials. Indeed, the processes requiring chemical reactions or intrinsic properties like anisotropic electric response are chemically dependent, whereas others are mostly based on the physical properties of the nanosheets such as their dimensions, like magnetic fields, freeze-casting, filtration, etc. Furthermore, the methods reviewed here are representative of the most commonly used methods and have numerous variations in the literature. Although some can produce bulk samples, couple several materials or have heterogenous alignment patterns, one common limitation of these methods is their inability so far, to decouple the final material shape with the local microstructure. This limits the potential for design and the fabrication of complex structures. Without design flexibility, giving a bright future for energy devices and others with boosted performances.
materials. To implement these achievements into a functional device with enhanced performance, a realistic 3D object or prototype is highly demanded. However, it is challenging to translate the exceptional properties of 2D materials into end structures for specific applications, because it involves assembling and upscaling the oriented microstructure for target properties. For example, it may be necessary to add a layer of glue between components processed separately, preventing intimate bonding between the functional parts and decrease in properties. In this area, 3D printing is a potential solution under the spotlight and a few reviews discuss about the 3D printing of 2D nanomaterials. However, these reviews miss the importance of 2D nanomaterials alignment and how the combination of 3D printing with alignment could further induce new and enhanced functionalities. In the following section, we therefore review 2D nanomaterials alignment supported by 3D printing and discuss how 3D printing can be expected really fabricate devices with high performance and/or new functionalities.

4.1 Advances in 3D printing

3D printing, or interchangeably called additive manufacturing (AM), refers to the fabrication process of building 3D structure in a layer-by-layer manner. This fabrication strategy allows customizable computer-aided design (CAD) and precise control of complex patterns from printable inks, for example, containing 2D nanosheets distributed in a matrix. One remarkable advantage of 3D printing over most conventional fabrication processes is the large design freedom. Indeed, the starting materials, 3D printing equipment, final structures, complexity, dimensions, and postprocessing methods can be tailored as desired. As a result, development in the field grows rapidly and has attracted increasing attention from both scientific and industrial communities in the late decade. 3D printing also allows the fabrication of complex, hierarchical structures with as much diversity as found in biological materials such as those shown in Fig. 1. 2D nanomaterials can therefore be integrated in nano, micro, and macroscopic structures, as illustrated in Fig. 19. If some of the common processes have numerous advantages for specific applications, for example for producing homogeneous coatings, fast production of thin films, nearly defect-free 2D nanomaterials, etc., 3D printing technologies open the avenue for the design and fabrication of materials, using one single method, but for potentially any application. More specifically, when it comes to 2D nanomaterials assembly, 3D printing technology reveals unique advantages over the standard processes in the following aspects: (i) local microstructures: the embedded particles can be locally reoriented during printing process or the postprocessing, with or without assistance of external forces such as the magnetic, electrical, or acoustic fields. (ii) multimaterial structures: heterogeneous materials compositions can be combined and fabricated synchronously during printing. (iii) complex shapes: benefiting from the layer-by-layer printing manner, complexity and diversity of the shapes can be broadened, especially for those with hollow structures and intricate interconnections. (iv) scale up: the dimensions and defined geometries of the printed architectures can be easily customized, enabling the fabrication of scalable
products. The 3D printing methods used for 2D nanomaterials are presented in the following section.

4.2 3D printing combined with alignment

First described in 1980s by Charles Hull regarding the stereolithography (SLA) process, 3D printing technology has evolved into multiple printing forms such as the inkjet printing, direct ink writing, powder bed fusion, selective laser sintering and so on.261-268 Overall, 3D printing techniques can mainly be classified into three types based on the materials feedstock: slurry-based, powder-based and bulk solid-supported. Each printing method possesses its own technical features in terms of equipment setup, feedstock material requirement, printing advantages and limitations. The recent progress in 3D printing has been summarized in a few comprehensive reviews.262-264,268-271 A few works report the use of fused deposition modelling (FDM) using graphene but the fabrication of thermoplastic filaments with homogeneously distributed 2D nanosheets is challenging.272,273 In FDM, the thermoplastic filament is heated and extruded through a nozzle on a substrate where it cools down to solidify. Inkjet printing has also been applied to 2D nanomaterial liquid suspensions but yields horizontal alignment.274 Obtaining vertically oriented nanosheets is difficult due to the capillary forces that develop during solvent evaporation in the deposited droplets. One recent paper reported on the drop-on-demand of purposely oriented 2D nanomaterials by adding a magnetic field. The success of the method depended on the concentration of particles in the ink deposited.275 Moreover, SLA has also been used with 2D nanomaterials.276,277 In SLA, a liquid suspension containing the 2D nanosheets and a UV-curable liquid is locally cured using UV light. Using local, sequential curing, SLA has been successfully applied in conjunction with magnetic fields to locally orient 2D nanosheets.278 Also, in SLA, graphene could be horizontally oriented simply by gravitational force during printing.279

Furthermore, the orientation of 2D nanomaterials has been achieved by combining 3D printing techniques with external magnetic field, electric field and temperature gradient, to introduce particle alignment in a programmable fashion.276,280 Martin et al. utilized the 3D magnetic printing method to fabricate complex oriented architectures using anisotropic 2D particles.281 The particles were oriented and patterned during printing using magnetic fields, where a digital light processor was used to cure the resin (Fig. 20a1-a3). Further, applying temperature gradient by freeze casting is also a feasible way to create desirable alignment in 3D printing.282 Zhang et al. developed the freeze casting assisted 3D printing of graphene aerogels from a drop-on-demand inkjet printer (Fig. 20b1-b4).282 Freeze casting provides rapid freezing and can manipulate the dispersed graphene orientation along the freezing direction. Thanks to the anisotropic ice crystal growth, the low viscous Newtonian graphene suspension can be printed into highly ordered assemblies as the graphene nanosheets are squeezed between the ice crystals. The printed graphene aerogel obtained presented ultralight densities with high compressibility, demonstrating excellent mechanical robustness. At the same time, the graphene macroscopic material with aligned microstructure offers high electrical conductivity and potential anisotropic thermal insulation properties for future applications.

The direct ink writing (DIW) 3D printing method is privileged for 2D nanomaterials given its ability to print from homogeneously dispersed liquid suspensions. In the following paragraphs, we discuss the DIW method applied to slurries containing 2D nanomaterials and showing multiple orientation control. DIW is an extrusion-based 3D printing technique. In this process, the 2D nanosheets are first homogeneously dispersed in a liquid polymer or solvent to produce an ink. As shown in Fig. 20c, the as-prepared ink is extruded from a printing nozzle as a continuous filament, and deposited in a layer-by-layer manner following a predefined pattern, just as directly “writing”.268,283,284 Then, the printed filaments are consolidated by curing under heat or light, other chemical reactions, dried or frozen, depending on the matrix composition used in the ink. As the quality of final printed parts is entirely determined by the rheological properties of the ink, a wide range of 2D nanomaterials can be obtained. Pastes, solutions, and hydrogels have been showed to be printable using DIW.267,285,286 Obtaining the proper rheological properties for the ink is paramount for successful printing, which is closely related to the filler concentration. To secure this printability, the ink has to exhibit the following key properties (Fig. 20d): shear thinning and viscoelasticity. Indeed, extrusion requires reasonably low viscosity of the ink. Thus, a viscosity decreasing with the applied shear rate is necessary. A viscosity ranging from 0.1 to 10^2 Pa·s is recommended to get smooth printing.268,283,287 In addition, the ink should have viscoelasticity to guarantee shape-retention and stability of the printed part. The elastic (or storage) modulus (G’) should be lower than the loss modulus (G’’), shear, but should rapidly recover to the opposite (G’’ > G’) once the shear force is removed.288 The behavior of such viscous ink flow is usually described by the Herschel-Bulkley model:289

\[ \tau = \tau_y + \text{K}\gamma^n \]

where \( \tau \) is the shear stress, \( \tau_y \) is the yield stress, \( K \) is the viscosity parameter, \( \gamma \) is the shear rate, and \( n \) is the shear thinning exponent (n<1). In this model, the yield stress is the minimum shear stress above which the ink flows. In case of a shear stress lower than the yield stress, the fluid behaves like a solid material.290-292

Having described the DIW printing method, we report how DIW has been used for 2D nanomaterial alignment. The 2D nanosheets dispersed in the ink can be manipulated by external forces or driven by self-assembly when the ink is still liquid, in the barrel, during extrusion, or in the printed parts and before consolidation by post-processing. The ability to locally control the orientation can in turn tune the local properties within the whole 3D part. For example, for 2D nanomaterials with considerable aspect ratio, the alignment can be induced by shear force along the printing direction.293,294 Liang et al. proposed a general method to fabricate vertically aligned 2D
As shown in Fig. 20e1 and 20e2, orientation of 2D BNNSs could be induced by the high shear force generated during extrusion of the ink. As a result, the 2D BNNSs were assembled along the vertical direction, which demonstrated outstanding thermal conductivity in the out-of-plane direction (Fig. 20e3). This shear force assisted printing strategy has been expanded to other 2D nanomaterials such as graphene and MoS$_2$ and can also be upscaled into macroscopic arrays (Fig. 20e4). In addition, Jambhulkar et al. demonstrated the orientation of 2D MXene nanoparticles by capillarity-driven DIW.\(^\text{295}\) In this case, a patterned substrate with microchannels was fabricated before printing, into which a MXene/ethanol suspension was spread (Fig. 20f1). The high capillary forces generated at the entry of the microchannels overcome the gravity, leading to the flow of MXenes in the microchannels. The Reynolds number, \(R_e\), is an index used to describe fluid flow and is key in this process.

\[
R_e = \frac{\rho v L}{\mu}
\]

where \(\rho\) is the fluid density, \(v\) is the fluid velocity, \(L\) is the characteristic linear length, and \(\mu\) is the viscosity of the fluid. A low \(R_e\) (\(R_e \ll 1\)) indicates a laminar flow within the microchannels and is suggested to be the main driving force to MXene nanosheet alignment retained after the subsequent evaporation of the solvent (Fig. 20f2, f3).\(^\text{295-297}\)

In summary, DIW is a highly tunable method that further expands the already large freedom degree of 3D printing by providing alignment control. This permits concomitant design of the shape and of the properties. Indeed, by providing a 3D shape with intricate microstructural features and design capabilities, these methods will enable us to make one step forward towards functional devices using 2D nanomaterials. One limitation however is the concentration of 2D nanosheet in the final material that is limited by the rheological properties. Indeed, it is known that increasing concentration of nanoparticles lead to jamming of suspensions. In the case of anisotropic nanosheets of high aspect ratio, this concentration is further decreased. Other points of improvement in DIW are interfilament binding that might compromise the performances of the 3D part, and nanosheet deformation which might reduce their intrinsic properties. Nevertheless, performing 3D objects can now be obtained and tested for real applications.

4.3 Beyond alignment control

The capability of harnessing local structures using 3D printing has potential for developing advanced materials and multifunctional devices. Indeed, we have seen in the section 2 of this review how orienting 2D materials into specific directions could enhance the performance of various functional devices. But the potential of 3D printing goes beyond its capability to create 3D shapes and controlling the local particle orientation. In view of creating multifunctional devices, another benefit of 3D printing is that inks of various chemical compositions can be printed in the same part. This is referred to as multimaterial 3D printing. This could for example lead to the fabrication of devices where the sensor is integrated in a device along with a battery or a supercapacitor, so as to release energy upon a specific external stimulus. It could also be used simply to create compact devices while maintaining low weight, to reduce the volume and payload for automobile or aerospace applications. In addition to this, 3D printed parts with local orientation and composition can induce new properties in the object, which result from the microstructural control and not entirely on the intrinsic properties of the filler. The most obvious of these new properties is self-shaping, 3D printing with time-varying morphing or performance variations is referred to as 4D printing. With the local orientational and compositional control, it is therefore possible to talk about 6D printing.299 These aspects are reviewed and discussed in the following sections for the specific case of 2D nanomaterials.

4.3.1 Multimaterial fabrication

Recent advances in 3D printing have revealed the possibility of multimaterial fabrication. Thanks to this unique capability, 3D printing is no longer limited to shaping and offers a broader imagination space for design and multifunctionality. Multimateriality in devices is thought as a means to increase sustainability thanks to the reduction of processing steps, waste material, and increase in functionalities within a small volume.294 For example, Kokkinis et al. established the material magnetically assisted DIW with alumina platelet orientation.300 The DIW printer was equipped with individual syringes and two-component dispenser to extrude different compositions during printing combined with local control over the building blocks (Fig. 21a). The inks, containing magnetized alumina platelets with fumed silica in resin (Fig. 21b,c), were designed to have printable rheological behaviors. Subsequent control of particle alignment was achieved by applying an external rotating magnetic field before consolidation (Fig. 21d). As a result, the printed macrostructure could be programmed with heterogeneous microstructures through locally tailored particle orientation and multimaterial compositions, as shown in Fig. 21e-g. Moreover, Skylar-Scott et al. achieved soft matter assembly by multimaterial multinozzle DIW.301 The ideal DIW system for multimaterial 3D printing possesses multiple printheads that extrude filaments of various compositions at a sufficiently high switching frequency between the compositions. The multimaterial nozzle can print different compositions within a single continuous filament, a pattern of filaments, or different parts in a macrostructure, which further broadens the design and manufacturing in complex motifs. Hardin et al. also demonstrated multimaterial 3D printing by developing a multimaterial microfluidic printhead for DIW.302 The microfluidic printhead design enabled printing multimaterials from the same nozzle in seamlessly switching manner. This programmable multimaterial fabrication method demonstrates the chances for building architectures with encoded local compositions for multifunctional applications. Some issues still remain, such as local mixing between the different compositions which can lead to desired or undesired compositional gradients. Also, interfacial bonding between the different inks is important to be maintained through-out the processing stages to prevent delamination of the macrostructure at a later stage. More recently, the concept of introducing complex gradient design is implemented in multimaterial 3D printing to reduce the interface mismatches in heterogeneous materials. With gradient structure, the local mechanical properties of printed products can be altered to prevent premature failure of device, for example, to relieve the stress concentration.321 The point of interfacial bonding is rather challenging when anisotropic, local orientations is added to it because of the anisotropic shrinkage that occurs due to temperature or curing, or other discrepancy between each material. These challenges could be mitigated by using inks suspending 2D nanoparticles of various chemistries within the same matrix, and by consolidated the parts via methods that do not use temperature, curing, or drying. In addition, the gradient 3D printing provides the capability of better manipulating local material compositions from functionally graded materials (FGMs) where the material property can vary spatially in 3D space, shedding light on wider design space and optimized functions in 3D printing.322

4.3.2 4D printing

The concept of 4D printing was initially established by Tibbits in 2013.303 4D printing allows the time-dependent evolution of the 3D printed shape or property by intentionally encoding this time dependence into the part through the 3D printing process.269,270,304-307 Generally, the time-dependent change is
triggered by an internal or external stimulus, such as temperature, magnetic field, electric field, particle orientation and pressure.\textsuperscript{228,308-313} For example, one typical strategy to encode shape change in a 3D printed object is by orienting nanofillers in perpendicular directions in a bilayer and using a matrix that changes its volume in response to an external stimulus. One illustration of such shape change has been realized by 3D printing anisotropic cellulose fibrils in a soft acrylamide matrix.\textsuperscript{314} During printing, the cellulose fibrils within the hydrogel composite align due to the shear force (Fig. 21h). Therefore, the printed object had anisotropic elastic and swelling properties tailored thanks to the local control of the filler orientation, which lead to its morphing under hydration (Fig. 21i-k).

In summary, the rapid development of 3D printing technologies has the potential to further unlock the advantages of 2D nanomaterials from nanoscale to microscale and up to the macroscale. 3D printing can be efficiently combined with deliberate local 2D nanosheets orientations, multimaterial compositions and time-dependent properties. The capability of controlling local compositions and microstructural alignment in 3D parts of defined shapes could therefore allow the development of new advanced, smart and multifunctional devices. The following section discusses what could be anticipated exciting prospects and what challenges still need to be faced to this aim.

5. Anticipated prospects and remaining challenges

The aforementioned processing techniques demonstrate the potential of harnessing 2D nanomaterial alignment into desirable assembly patterns, where the local orientation can be horizontal, vertical, heterogeneous, or purposely set in any orientation. Furthermore, 3D printing technologies enable upscaling with the possibility of using multiple local compositions or microstructural orientations. We have seen in the section 2 of this review, that oriented 2D nanomaterials significantly boost the performance of sensing, thermoelectric and electrochemical devices. Given all these advances in manufacturing and local orientation and composition, we have to pose the question of how these advances be leveraged for realistic, smart, multifunctional applications? What remains to be investigated or what could be the difficulties to overcome? These open questions are discussed in the following.

5.1 Anticipated prospects

![Fig. 21](image-url)
3D printing of 2D nanomaterials already can create 3D shapes with local design, composition and time-dependent properties. 3D printing can even be further augmented with tunable density by controlling the porosity within the printed filaments in DIW, by adding a sacrificial porogen or a foaming agent, for example. Intentionally introducing nano or microporosity could increase the surface area, contribute to efficient molecule transportation and diffusion, to further augment the functional properties. Therefore, proper addition of porosity could lead to objects with lighter weight but similar, if not increased, performance. This would result in the use of less material feedstock and in turn allow less waste material generation. Another advantage of controlled local porosity, orientation, and composition is the ability to design entirely hierarchical structures from the nanoscopic scale to the macroscopic scale, in a fashion that can be paralleled with the natural materials discussed in Fig. 1 in the introduction of this review. Hierarchical designs are indeed known to enhance simultaneously functional and structural properties of natural materials by inducing microstructure-related mechanisms. One common example of hierarchical design is the helicoidal arrangement of nanoparticles in the so-called Bouligand structure in the Mantis shrimp, that conveys strength and toughness, while nanochannels spread throughout the material allowing ion flow. One could imagine such similar structure where the nanoparticles in the natural structure are replaced with vertically oriented 2D nanosheets. In this case it could be that the resulting materials could exhibit lower tortuosity, leading to the functionalities reported in section 2 of this review, in combination to high mechanical performance. The dual presence of enhanced functional and structural properties is important in all devices. Indeed, in operation, devices also need to withstand loads, shocks, vibrations, stresses, etc.

Furthermore, local microstructural design capability also opens up new applications. One could imagine conformable batteries or supercapacitors with complex intricate shapes that integrate inside or around the apparatus to which they supply energy. To maintain the performance in curved designs, for example, the microstructure should be adapted accordingly. One could be interested in this capability when designing compact devices of high surface to volume ratio and low weight. This kind of demands are interesting in autonomous vehicles, in portable biomedical devices and other robotic applications, for example. Finally, the multimaterial capability of 3D printing would permit the design of multiple devices integrated within one 3D object. Fig. 22 illustrates the design of a multifunctional smart device. Within one 3D device, multiple functionalities can be fused and cooperate automatically, for example, sensing external heat stimulus, then generating electric energy from the waste heat through a thermoelectric module, and later harvesting the electric energy by a battery or a supercapacitor. To add more customizable functions, the individual devices could be simply printed next to each other using one unique process, therefore reducing time, manpower, and space for their fabrication. The devices could also be integrated more intimately at a smaller scale, nano or micro, so that their functions are related to each other. Other concrete examples of this concept might be a battery that changes shape depending on an external stimulus and that in turn changes its battery performance, or a supercapacitor with an integrated sensor able to inform on the status of the capacitor or to change its performance depending on external parameter. Materials with embodied and interacting functions are referred to as ‘robotic materials’ and could unlock numerous opportunities for passive actuation of functional devices and materials computation.
The blooming studies on synthesis and assembly processing of 2D nanomaterials in the past decades have triggered explosive progress in this research community and brought great opportunities in diverse application fields. Introducing alignment and designed microstructural patterns with 2D nanomaterials have shown unpredictable capabilities to further amplify the functionalities. Established, state-of-art advances demonstrate indeed the great potential of orientated 2D materials in future functional designs and applications. Although these developments lead to exciting, anticipated ideas, number of challenges remain. Some of these challenges are now discussed.

5.2 Remaining challenges

The first challenge to realize the anticipated prospects is the obtention of a scalable material feedstock of high quality. In terms of 2D nanomaterial synthesis, the current nanomaterials produced through top-down exfoliation and bottom-to-up growth still have a yield far from what is needed for industrial application or commercialization. Furthermore, the quality of the produced 2D nanomaterials is greatly affected by the fabrication methods. For example, mechanical processes may lead to wrinkling of the nanosheets, reducing their properties in plane. At the same time, chemical processes use harsh chemicals and solvents that are not sustainable or safe, and for which waste management and cost are demanding. The synthesis of the 2D nanomaterials also determines their dimensions, anisotropy, surface functionalization capability, etc. The 2D nanomaterial quality, composition and size, etc., greatly affect their nanoscopic intrinsic properties. Hence, managing high material quality and quantity are essential for good performances. To achieve high yield, quality, and to limit the use of solvents and waste chemicals, biosynthesis and green synthesis should be further explored. Promising results have been obtained for the biosynthesis of graphene using biomolecules, green synthesis of graphene via electrochemical processes, and should be transposed for the other 2D nanomaterials.
Furthermore, to achieve ideal tunability and high performance of devices based on 2D nanomaterials oriented in multiple directions, it is necessary to unravel the related microstructure-properties relationships. The complex relationships between intrinsic material property, defects, assembled structure, orientation degree, and connectivity are indeed intrinsically related to the final performances. For example, giving a specific application, the suitable material selection, high material quality and controlled defects level can bring higher chances for desirable material performances. Moreover, the assembly strategy plays a critical role in further deciding how the final performances are yielded. With better understanding of the internal interactions, 2D nanomaterials could then be rationally modified and arranged into favorable structures using the advanced processing methods or printing technologies described in this review. Computation modelling and simulations, for example using density-functional theory (DFT) modelling, Monte-Carlo simulations and other computation methods should be further used to explore and understand the mechanisms at the nanoscopic and microscopic scales and enable hierarchical design.

Finally, the grand challenge as well as ultimate goal of designing oriented 2D nanomaterials locally and in 3D macrostructures is to leverage their exceptional properties for multifunctional devices. We have seen how 3D printing with local orientational control could open up the design capabilities by provide at least 6 degrees of freedom. How to make best use of such a large design space for target properties? Open to find among all the possible, the best microstructure, composition, local orientation and so forth for realizing the highest performance? These are challenging questions to address which could be tackled with the establishment of open access data bases, machine learning and artificial intelligence as well as smart reverse engineering optimization methods.

6. Conclusions

The emerging development of 2D nanomaterials such as graphene, BNNS, MXenes, TMDs, etc. sheds light on the promising future applications. Controlled local orientation of 2D nanomaterials plays an increasingly important role in realizing high performances for multiple applications. In this paper, we first reported several examples that demonstrate the advantages of orienting 2D nanomaterials in specific directions for enhancing the performance of sensing, thermoelectric and electrochemical devices. We then systematically reviewed the state-of-art processing methods to induce controlled alignment of 2D nanomaterials in desired manner, namely with horizontal, vertical, heterogeneous and arbitrary orientation. Recent advances in 3D printing techniques were then discussed and highlighted the possibility of upscaling 2D nanomaterial assembly from nano to macro scales, while further opening other advantages such as multimaterial fabrication and programmable time-dependent evolution. Although 2D nanomaterials with delicately designed local orientations have demonstrated their potential for inducing higher material performances in multiple functional applications, there are multiple challenges to overcome to really create the next generation of devices. We suggested "enthusiastic future prospects in this research field as well as pinpointed a few challenges to solve to realize them. From the rapid development of 2D nanomaterials and orientation assembly technology, we can see the great potential in the currently established functional applications and future breakthrough in harnessing the complexity and multifunctionality.
