(Dated: January 28, 2020)

The discovery of gravitational waves has confirmed old theoretical predictions that binary systems formed with compact stars play a crucial role not only for cosmology and nuclear astrophysics [1]. As a byproduct of these and subsequent observations, it is now clear that neutron-star mergers can be a competitive site for the production of half of the elements heavier than iron in the universe following a sequence of fast neutron capture reactions known as the \textit{r}-process. In this article we discuss an effect which has been so far neglected in calculations of \textit{r}-process nucleosynthesis in neutron star mergers. We show that the corrections due to the neutron environment even at relatively small neutron densities, within the bounds of numerical hydrodynamical simulations of neutron star mergers and after the onset of the \textit{r}-process, are non-negligible and need to be taken into account to accurately describe the elemental abundance as determined by observations.

\textbf{Introduction.} The rapid neutron capture process (\textit{r}-process) is thought to be responsible for about half of all elements heavier than iron. However, the properties of the nuclei and nuclear reactions involved in the \textit{r}-process are not well known. Besides, its astrophysical site is not yet clearly identified. Neutron star mergers and supernova explosions are possible stellar sites candidates for the \textit{r}-process, but it is uncertain which of the two sites are more effective [1–3]. Neutron star mergers are promising nucleosynthesis sites of heavy elements, because a large amount of neutron-rich matter is probably ejected during merger [1–7]. For neutron star mergers, the ejecta medium has an electron fraction, or electron number density per baryon density, in the range \(0.05 \lesssim Y_e \lesssim 0.5\), irrespective of the equation of state (EoS). This might explain the \textit{r}-process abundance pattern for nuclear mass numbers \(A \gtrsim 90\) observed in the solar system and in metal-poor stars. In the case of black-hole (BH) and NS mergers, the dynamical ejecta contains a low electron number density, \(Y_e \lesssim 0.1\), and heavy elements \(A \gtrsim 130\) are produced in the \textit{r}-process [8]. But the \textit{r}-process can create all elements up to \(A \approx 250\), beyond the third peak of elemental abundance. It is also possible that very heavy nuclides with \(A > 300\) can be produced due to the very neutron-rich environment. Those nuclides are unstable to spontaneous or neutron-induced fission leading to a fission cycle that continues until the free neutrons are exhausted [1–8].

In order to calculate the nucleosynthesis in NS-NS or BH-NS ejecta scenarios one needs to know basic nuclear properties, such as nuclear masses, \(\beta\)-decay lifetimes, \((n, \gamma)\) and \((\gamma, n)\) reaction rates, and a solid knowledge of nucleon capture cross sections is needed. A novel phenomenon considered in this letter is the influence of the neutron density on the \((n, \gamma)\) and \((\gamma, n)\) rates. We show that a substantial reduction of theses cross sections emerges when the \textit{r}-process nuclei are immersed in a neutron background even for the moderately low densities in the ejecta of the NS mergers. In fact, simulations have shown that neutron densities up to about \(\rho \sim 10^{-1} - 10^{-2}\)\(\rho_0\) are possible during the nucleosynthesis process following the merger stage, where \(\rho_0 = 0.16\) \(\text{fm}^{-3}\) is the nuclear saturation density [9–12]. The consequences of the neutron background on the reaction rates has not been studied so far. But a full consideration of this phenomenon, using a hydrodynamical simulation coupled to a nucleosynthesis reaction network path, is beyond the scope of the present work. Our objective is to explore how the presence of the surrounding neutron medium will impact the cross sections and, if the impact is shown to be important, it certainly needs to be considered in a full \textit{r}-process calculation of NS-NS or BH-NS mergers.

\textbf{Theoretical framework.} Our approach is based on a standard nuclear reaction theory. We will consider the total neutron-nucleus induced cross section usually dominated by \(\gamma\) emission for low neutron energies. We use the following expression for the total neutron capture cross section in free space:

\begin{equation}
\sigma(E) = -\frac{K}{E} \langle \chi^{(+)} | W | \chi^{(+)} \rangle,
\end{equation}

where \(K\) and \(E\) is the center-of-mass scattering momentum and energy, respectively, and \(W\) is the imaginary part of the neutron-nucleus one-body potential \(U\). The neutron scattering (distorted) wave \(\chi^{(+)}\) is a solution of the Schrödinger equation for the potential \(U\) under the outgoing boundary condition. With the total reaction cross section, one can easily obtain the reaction rate by a folding of its energy (velocity) dependence with the relative velocities of the neutron and the nuclei in the medium, assumed to follow a Maxwell-Boltzman distribution.

We assume that neutrons from the environment are homogeneously distributed around the reacting (neutron+nucleus) system. These neutrons will be denoted here by background neutrons (BN). We further assume that the BN are not substantially affected by the nucleus. This allows one to estimate the additional potential, besides the neutron-nucleus potential \(U\), that the incoming neutron feels under the influence of the

\textsuperscript{*}kazuyuki@rcnp.osaka-u.ac.jp
\textsuperscript{†}carlos.bertulani@tamuc.edu
BN, which we call an environment mean potential (EMP), as
\[ \mathbf{V}_{EMP}(r) = \int \mathbf{A}P(r-r')\nu_{nn}(|r-r'|) \text{d}r'. \tag{2} \]

Here, \( \nu_{nn} \) is a neutron-neutron (\( nn \)) interaction, \( \Omega \) is a macroscopic volume surrounding the reaction system, \( A \) is the number of neutrons inside \( \Omega \), and \( \mathbf{P}(r-r') \) is a probability density that one finds neutron at \( r' \) when the incoming neutron is located at \( r \). In terms of these definitions, \( \mathbf{P}\Omega \) is a probability measure of the influence of the BN by the neutrons within a distance \( r-r' \) inside the volume \( \Omega \). Due to the saturation of the nucleon-nucleon force, the calculation of \( V_{EMP} \) converges quickly for distances \( s = |r-r'| \) larger than \( \sim 3 \text{ fm} \).

To evaluate \( \mathbf{P} \) we consider the probability density \( P \) to find particle 1 at \( r_1 \) and particle 2 at \( r_2 \) when the \( A \) lowest (continuum) single particle (s.p.) states are occupied. Using a Slater determinant for these states, one gets
\[ P(r_1, r_2) = \int \psi^*(1, \cdots A)\psi(1, \cdots A)\text{d}r_3\text{d}r_4 \cdots \text{d}r_A \]
\[ = \frac{1}{A(A-1)} \sum_{\alpha,\beta} \frac{|\phi_\alpha(1)\phi_\beta(2)| - |\phi_\beta(1)\phi_\alpha(2)|^2}{|\phi_\alpha(1)\phi_\beta(2)|}, \tag{3} \]
where \( \psi \) is an antisymmetrized A-body wave function and \( \phi \) denotes a s.p. state. \( P \) is normalized as \( \int_\Omega P(r_1)\text{d}r_2 = 1 \). The relation between the two probability densities is
\[ \mathbf{P}(s) = \int \text{d}r_1 P(r_1, r_2). \tag{4} \]
We assume that each neutron-neutron pair is in a s-wave scattering state with \( S = 0 \) and \( T = 1 \). At low temperatures, we can also safely assume that all neutron states in the continuum are occupied up to the Fermi momentum \( k_F \), and the following relation with the number density \( \rho = A/\Omega \) of the BN arises: \( 4\pi k_F^3/3 = \pi^2 A/\Omega \). Using plane waves for the relative motion between the neutrons, \( \phi_\alpha = (1/\sqrt{\Omega}) \exp(ik\cdot r) \), it is straightforward to show that for \( A \gg 1 \), the probability entering Eq. (2) is given by [13]
\[ \mathbf{P}(s) = \frac{1}{\Omega} \left( 1 - \left[ \frac{3}{(k_F s)^2} \left( \frac{\sin(k_F s)}{k_F s} - \cos(k_F s) \right) \right]^2 \right), \tag{5} \]
which does not depend on where one of the two particles is located but only on their separation distance \( s = |r-r'| \).

The Pauli blocking probability due to the BN, \( \mathbf{P}(s)\Omega \), is shown in Fig. 1 for four different values of \( \rho/\rho_0 = 1, 10^{-1}, 10^{-2}, \) and \( 10^{-3} \) by the solid, dash-dotted, dashed, and dotted lines, respectively. The Pauli blocking creates an effective “wound” at the neutron-neutron scattering wave function for neutron-neutron separation distances \( s < 2/k_F \) (\( \sim 1.4 \text{ fm} \) at saturation density \( \rho_0 \)). As seen in Fig. 1, at lower density, the spatial region affected by Pauli blocking becomes wider because of the uncertainty principle. Note, however, that the effect of the BN in the low density limit is negligible because Eq. (2) is proportional to \( \rho \). If the Pauli principle is ignored, \( \mathbf{P}(s)\Omega = 1 \) and, equivalently, \( \mathbf{A}\mathbf{P}(s) = \rho \).

Integrating Eq. (2), and because of the finite range of the neutron-neutron interaction, one finds that the net effect of the BN on the neutron-nucleus scattering wave is to effectively shift the scattering energy \( E \) by a nearly constant amount,
\[ E \rightarrow E + \epsilon_{EMP}. \tag{6} \]
Notice that even in the absence of Pauli blocking, medium effects would have to be present in the classical limit \( \mathbf{P}(s)\Omega = 1 \). In this case,
\[ \epsilon_{EMP} \rightarrow -\rho \bar{v}_{nn}, \tag{7} \]
where \( \bar{v}_{nn} \) is the volume integral of \( v_{nn} \). The effect of Pauli blocking is to reduce this energy shift, allowing the neutrons to stream more freely within a denser region. This effect is well known in nuclear physics, justifying the use of the Fermi gas model to describe some of the gross nuclear properties. The novel idea in our work is to extend these known features to the case of neutron-nucleus scattering in the presence of a neutron background environment.

According to the energy shift approximation introduced above, the neutron capture reaction rate in a dense neutron environment is corrected to
\[ \langle \sigma v \rangle_{EMP} = \left( \frac{8}{\mu \pi} \right)^{1/2} \frac{N_A}{(k_B T)^{3/2}} \int e^{-E/k_B T} \sigma(E + \epsilon_{EMP}) \text{d}E \times \sqrt{E(E + \epsilon_{EMP})}. \tag{8} \]

This method allows one to quickly estimate the effects of the BN in a simple fashion, also highlighting its dependence on the details of the nucleon-nucleon interaction at short distances. A very interesting outcome of this result is that, at very low energies, when \( \sigma \propto 1/v \), where \( v \) is the neutron velocity, one gets \( \langle \sigma v \rangle_{EMP} = \langle \sigma v \rangle_{free} \). The \( 1/v \) law emerges directly from Eq. (1) since the matrix element on its right asymptotically reaches a constant value as \( E \to 0 \). Therefore,
at very low energies, Pauli blocking by the environment neutrons effectively keeps unchanged the reaction rates, as if the incoming neutron-nucleus reaction energy remains unaltered.

Application to neutron capture on Ni isotopes. In the following discussion, we consider neutron capture processes by $^{58}$Ni and $^{78}$Ni by employing the Koning and Derocho global optical potential for $U$, needed to calculate the scattering waves entering Eq. (1). The choices for these two systems are not special, but just reflecting standard study cases. Also, we would like to check if there is any effect due to an increase of the neutron number of the nucleus. We will conclude that it does not have a substantial change and that the effect of the BN on the reaction rate has very general features common to most neutron-capture reactions in dense environments. Except for the extremely low energies of a few eV (thermal neutrons), there is also a substantial deviation form the 1/$v$ law, specially for the energies involved in a stellar environment. For the neutron-neutron interaction $v_{nn}$ in the $(S, T) = (0, 1)$ channel, we use the Argonne V8’ (AV8’) interaction, the Minnesota interaction, and the Michigan three-range Yukawa interaction based on the Reid potential (the M3Y-Reid interaction).

In Fig. 2 the nucleon-nucleon interaction, $v_{nn}$, as a function of the neutron-neutron distance $r$ is shown by thin lines. The effective interaction, with the effects of the neutron environment, $v_{nn}^{\text{eff}}$ for $\rho_{\text{env}} = 10^{-1}\rho_0$ is shown by thick lines. The dotted, solid, and dashed-dotted lines correspond to the AV8’, Minnesota, and M3Y-Reid interactions, respectively. One sees the solid, dashed, and dotted lines correspond to the AV8’, Minnesota, and M3Y-Reid interactions, respectively. One sees why the interaction dependence is weakened in $v_{nn}^{\text{eff}}$. We can therefore expect that the EMP effect introduced in this work does not depend strongly on $v_{nn}^{\text{eff}}$.

In order to assess the influence of the environment BN we now turn to the neutron-nucleus scattering properties. Figure 3 shows the energy shift of the neutron-nucleus scattering energy, $\epsilon_{\text{EMP}}$, as a function of $\log_{10} \rho / \rho_0$. The meaning of the lines are similar as those in Fig. 2. But now the dashed lines show the results without the Pauli principle, that is, they represent the volume integrals $v_{nn}$ of the three $v_{nn}$ multiplied by $-\rho$. Comparing the three interactions, the magnitude of the $|\epsilon_{\text{EMP}}|$ for the AV8’ interaction is found to be smallest because it has the largest repulsive core. Once the Pauli blocking effect is considered (solid lines), this characteristic feature of the AV8’ interaction vanishes and the three $v_{nn}$ yield almost the same $\epsilon_{\text{EMP}}$. For the other two $v_{nn}$, Pauli blocking has no significant effect on $\epsilon_{\text{EMP}}$ for $\rho_{\text{env}} \lesssim 10^{-1}\rho_0$. At lower $\rho$, the “wound” on $v_{nn}$ develops further to larger $r$ and $\epsilon_{\text{EMP}}$ decreases significantly. This is the case also with the AV8’ for $\rho_{\text{env}} \lesssim 2 \times 10^{-2}\rho_0$. Inclusion of the Pauli principle is thus essential to estimate $\epsilon_{\text{EMP}}$. An important conclusion stemming from Fig. 3 is that there exist a non-negligible energy shift $\epsilon_{\text{EMP}}$ of about 500 (100) keV even at $\rho_{\text{env}} / \rho_0 = 10^{-2}$ ($3 \times 10^{-3}$).

We consider now the effect of the environment BN on the neutron capture rates. In Fig. 4, we show the integrand in Eq. (8) (a) for $^{58}$Ni and (b) for $^{78}$Ni, as a function of the neutron scattering energy $E$. The temperature is chosen as $T = 0.1$ GK and the BN environment densities are varied from $\rho / \rho_0 = 0$ to 0.05. In each panel, the solid, long-dashed, dashed, dotted, dash-dotted, and dash-dot-dotted lines, respectively, correspond to $\rho_{\text{env}} / \rho_0 = 0, 7 \times 10^{-4}, 3 \times 10^{-3}, 9 \times 10^{-5}, 1.5 \times 10^{-2}, 5 \times 10^{-2}$. These six densities yield for the energy shift due to the environment the values of $\epsilon_{\text{EMP}} = 0, 10, 100, 500, 1000, \text{and} 5000 \text{MeV}$ in that order. At low finite densities, $\epsilon_{\text{EMP}}$ reduces $\sigma$ quite signifi-
FIG. 4: The integrand in Eq. (8) (a) for $^{58}$Ni and (b) for $^{78}$Ni, as a function of the neutron scattering energy $E$. The temperature is chosen as $T = 0.1$ GK and the BN environment densities are varied from $\rho/\rho_0 = 0$ to 0.05.

significantly in the low energy region, while the weighting factor $w \equiv \sqrt{E/(E + \epsilon_{\text{EMP}})}$ increases. The change in $\sigma$ is saturated at a certain density because the energy dependence of $\sigma$ for $E > 200$ keV is quite small. On the other hand, $w$ keeps increasing as the density becomes higher. Thus, the net effect of $\epsilon_{\text{EMP}}$ on $f$ is determined by the energy dependence of $\sigma$, particularly at low energies. One sees from Fig. 4 that for the neutron capture by $^{58}$Ni, $\epsilon_{\text{EMP}}$ decreases $f$ for $0 < \rho_{\text{env}} \lesssim 9 \times 10^{-3}/\rho_0$ and increases $f$ for $\rho_{\text{env}} \gtrsim 9 \times 10^{-3}/\rho_0$. On the other hand, for the neutron capture by $^{78}$Ni, $f$ increases for $\rho_{\text{env}} \gtrsim 7 \times 10^{-4}/\rho_0$.

Finally, we show that the reaction rate $\langle \sigma v \rangle$ for $n-^{58}$Ni and $n-^{78}$Ni is substantially modified because of the energy shift $\epsilon_{\text{EMP}}$. These rates are displayed in Figs. 5(a) and (b), respectively. The horizontal axis is the temperature in units of GK and the correspondence between each line and the density is the same as in Fig. 4. The behavior of the reaction rates can be understood by looking at the energy shift $\epsilon_{\text{EMP}}$ dependence of $f$ discussed above. The change in the rate at $\rho_{\text{env}}/\rho_0 = 5 \times 10^{-2}$ is significantly large, which becomes even larger at higher density. It should be noted, however, that the central assumption made in this work, Eq. (2), will break down at some value of $\rho_{\text{env}}$ when it gets closer to the normal density $\rho_0$. A more careful treatment of the “background” neutrons that can be applied to $\rho_{\text{env}} \sim \rho_0$ will be interesting and important future work. Another remark is that the change in the reaction rate by the environment BN is expected for other nuclear reactions of various kinds. The energy shift $\epsilon_{\text{EMP}}$ will affect cross sections for proton-induced reactions in a very different way from that we have discussed here because the Coulomb penetrability dominates the cross section at low energies. In this case, the energy shift $\epsilon_{\text{EMP}}$ for $(S,T) = (1,0)$ must be evaluated. In addition, resonant capture processes can be affected by the energy shift $\epsilon_{\text{EMP}}$ significantly because it allows the reaction system to form resonant states at higher energies for which it is almost impossible to reach at the typical temperatures considered.

Conclusions and final remarks. We have considered the effect of environment neutrons in neutron capture reactions in dense environments. The effect is similar to that of electrons in dense stellar sites, such as those for which $\beta$-decay is blocked by the presence of the electrons in the final state, thus modifying the path of the r-process. In contrast to electron environments, in a dense neutron environment the $(n,\gamma)$ and $(\gamma,n)$ are also influenced by Pauli blocking and our results cast no doubt that this effect must considered in reaction network calculations for neutron star mergers involving equilibrium and non-equilibrium r-processes. A fundamental difference with the treatment of electron-rich environment is that the neutron background will also have a decisive influence in thermal statistical equilibrium conditions. Although in statistical equilibrium the $(n,\gamma)$ and $(\gamma,n)$ cross sections are not needed, the Pauli blocking of the emitted neutrons in the $(\gamma,n)$ process will modify the Saha-like equations for statistical equilibrium. This might be easy to incorporate in detailed calculations by following a similar energy-shift method as proposed in this article.
