We consider a theoretical model for the chiral smectic A twisted ribbons observed in assemblies of fd viruses condensed by depletion forces. The depletion interaction is modeled by an edge energy assumed to be proportional to the depletant polymer in solution. Our model is based on the Helfrich energy for surface bending and the de Gennes model of chiral smectic A liquid crystals with twist penetration at the edge. We consider two variants of this model, one with the conventional Helfrich Gaussian curvature term, and a second with saddle–splay energy. A mean field analysis of both models yields a first–order phase transition between ribbons and semi–infinite flat membranes as the edge energy is varied. The phase transition line and tilt angle profile are found to be nearly identical for the two models; the pitch of the ribbon, however, does show some differences. Our model yields good qualitative agreement with experimental observations if the sign of the Gaussian curvature or saddle–splay modulus is chosen to favor negative Gaussian curvature.

I. INTRODUCTION

Smectic A (Sm-A) layers expel twist and bend deformations, just as magnetic fields are expelled from bulk superconductors [1,2]. In analogy with the London penetration length, the typical distance to which a magnetic field penetrates into a superconductor, two penetration depths can be defined in Sm-A liquid crystals describing respectively the penetration of twist and bend deformations at the edges or around isolated defects of Sm-A layers. When a Sm-A sample is composed of chiral molecules (molecules without mirror symmetry), twist deformations appear intrinsically, driving the formation of novel structures, due to the competition of the twist deformations with the tendency of the molecules to build a perfect twist–free smectic layer [3]. When the layer forming tendency dominates, the twist is restricted to a band at the layer edge, but when the twist deformations are strong enough, simple flat membranes are replaced by a variety of twisted structures, including twisted ribbons, double helices, arrays of twist walls in membranes, and periodic arrays of pores. In this paper, we study a theoretical model for one result of this basic competition of ordering forces, the transition between flat disks and twisted ribbons.

Recently, there have been both experimental and theoretical studies to visualize and quantify the effects of twist and bend deformations on chiral smectic A (Sm-A*) single-layer membranes in the weak chirality limit, as well as investigating the relative stability of different geometries of membranes seen in experiments. These membranes are formed under certain conditions in aqueous solutions of filamentous virus particles and a non-binding polymer, which acts to condense the virus particles into dense phases by depletion forces. Barry et. al. have studied flat Sm-A* monolayer membranes in the form of disks composed of rodlike fd virus particles to measure the twist penetration length \( \lambda_t \) at the edges of the disks [4]. The persistence length of these viruses is 2.8 ± 0.7 \( \mu m \) and the length of fd viruses was around 1 \( \mu m \), making them nearly rigid rods [5]. Because they act like hard rods, the condensed phases they form due to the depletion force are mainly entropy driven [6, 7]. These viruses form cholesteric and Sm-A* phases with increasing concentration. The radii of the disks studied were tens of micrometers. Due to the length scale defined by the particle length, the twist penetration could be visualized using optical microscopy. Due to the tilting of the virus particles relative to the layer normal, in the twist penetration region, the twist could be measured by the resulting change in retardance of transmitted polarized light. The twist penetration length \( \lambda_t \) was determined to be about 0.5 \( \mu m \). Because the disks were relatively large compared to this, the twist penetration profile fit well to the analytic theory of twist penetration for a semi–infinite membrane, with the director tilting tangential to the edge of the membrane. From the estimated maximum tilt at the disk edge, the product of penetration length and cholesteric wave vector \( q \) was estimated as approximately \( q \lambda_t = 0.71 \), for the particular sample studied.

In analyzing the energy of the edge of a disk, there are two important terms, the bare edge energy, or line tension, of the edge, \( \gamma \), and the net reduction of free energy in the material near the edge due to the twist penetration. The line tension is controlled by the concentration of depletant polymer in solution. As this concentration is lowered, \( \gamma \) is reduced. In a simple analysis, if the second term then becomes larger than the first, then the net energy associated with the edge is negative, and the material will adopt a structure that maximizes the length of edge, relative to the area of flat disk. This can be achieved in several ways.

One mechanism, previously studied, is a transition from semi–infinite membranes to small disks as the struc-
ture that minimizes the mean free energy density of the system. The mean free energy density of small Sm-A* disks, which have both twist and bend deformations at the curved disk edge, has been calculated [8]. It is found that small disks with a twist/bend penetration length on the order of the disk radius are at least metastable relative to large disks upon reducing the line tension of the edge. The magnitude of the critical line tension at which a second–order phase transition occurs from semi–infinite membranes to small disks is affected by the magnitudes of the twist wave vector \( q \) and the twist penetration length \( \lambda_t \).

Rather than simple small disks, a diversity of structures is observed experimentally to replace large disks as the concentration of depletion agents is lowered [9].

In Sec. II C we consider an alternate model of the membrane where we replace the Gaussian curvature by splay playback; we compare the results of the two models of a twisted ribbon in Sec. III.

The de Gennes free energy density for the nematic–Sm-A* phase transition is given by:

\[
f_{NA} = \frac{r}{2} |\Psi|^2 + \frac{u}{4} |\Psi|^4 + D (\nabla - \frac{2\pi i}{d} \delta \hat{n}) |\Psi|^2 + \frac{1}{2} K_1 (\nabla \cdot \hat{n})^2 + \frac{1}{2} K_2 (\nabla \times \hat{n} - q)^2 + \frac{1}{2} K_3 (\nabla \times \hat{n})^2 \]

(4)

Here \( \Psi \) is the smectic order parameter, \( K_1, K_2 \) and \( K_3 \) denote the splay, twist, and bend Frank elastic constants respectively, \( q \) is magnitude of the spontaneous twist wave vector arising from molecular chirality, and \( \delta \hat{n} \) is the deviation of the director from the layer normal. In a bulk Sm-A* phase twist and bend distortions which are incompatible with constant interlayer spacing will be expelled; however, as noted by de Gennes both twist and bend can be introduced at layer edges or around defects by allowing local tilting of \( \hat{n} \) relative to the layer normal. Two penetration lengths can be introduced, \( \lambda_2 = (K_2/D)^{1/2} \) and \( \lambda_3 = (K_3/D)^{1/2} \), describing respectively the penetration lengths of twist and bend into the smectic phase.

In the limit where the smectic order parameter \( \Psi \) is uniform and nonzero (i.e., deep in the smectic A* phase) the de Gennes free energy density reduces (up to a constant) to:

\[
f_n = \frac{1}{2} K_1 (\nabla \cdot \hat{n})^2 + \frac{1}{2} K_2 (\nabla \times \hat{n} - q)^2 + \frac{1}{2} K_3 (\nabla \times \hat{n})^2 + \frac{1}{2} C \sin^2 \theta ,
\]

(5)

where \( \theta \) is the tilt angle of the director with respect to the layer normal and the tilt energy density \( C \) is proportional to the coupling \( D \) appearing in Eq. [4].
In the single Frank elastic constant approximation, \(K \equiv K_1 = K_2 = K_3\), which we will henceforth employ in the analysis of Eq. (11), \(f_n\) is given by:

\[
f_n = \frac{1}{2}K \left[ (\nabla \cdot \mathbf{n})^2 - 2q\mathbf{n} \cdot (\nabla \times \mathbf{n}) + (\nabla \times \mathbf{n})^2 + q^2 \right] + \frac{1}{2}C \sin^2 \theta. \tag{6}
\]

Mathematically, a membrane can be represented as a surface with position vector \(\mathbf{Y} = \mathbf{Y}(u_1, u_2)\) embedded in a three–dimensional Euclidean space, where \(u_1\) and \(u_2\) are real variables parameterizing the surface. To calculate the free energy of the membrane we need the following geometric quantities \([15, 16]\):

\[
\begin{align*}
\mathbf{Y}_i &\equiv \partial_i \mathbf{Y}, \quad \mathbf{Y}_{ij} \equiv \partial_i \partial_j \mathbf{Y} = \Gamma_{ij}^k \mathbf{Y}_k + L_{ij} \hat{\mathbf{N}}, \\
\partial_i \hat{\mathbf{N}} &\equiv \partial_N \mathbf{Y}_i \equiv -L_{ij} g^{jk} \mathbf{Y}_k, \\
g_{ij} &\equiv (g_{ij})^{-1}, \quad g \equiv \det g_{ij}, \\
L_{ij} &\equiv \mathbf{Y}_{ij} \cdot \hat{\mathbf{N}}, \quad L^i_j \equiv (L_{ij})^{-1}, \quad L \equiv \det L_{ij}.
\end{align*} \tag{7}
\]

The indices \(i, j, k = 1, 2\) (repeated indices being summed over), \(\partial_i \equiv \partial_{u_i}\), and \(\partial_N\) denotes the partial derivative in the normal direction \(\hat{\mathbf{N}}\). The completely symmetric tensors \(g_{ij}\) and \(L_{ij}\) are the first and second fundamental forms of the surface, respectively. The Christoffel symbols \(\Gamma_{ij}^k\) are defined by the relation \(\Gamma_{ij}^k = g^{kj} \partial_i \mathbf{Y}_j \cdot \mathbf{Y}_m\), and obey the symmetry property \(\Gamma_{ij}^k = \Gamma_{ji}^k\). The unit normal vector of the surface is given by

\[
\hat{\mathbf{N}} = \frac{\mathbf{Y}_1 \times \mathbf{Y}_2}{\sqrt{g}}. \tag{8}
\]

The Gaussian curvature \(K_G\), is given by:

\[
K_G = \frac{L}{g}, \tag{9}
\]

and the surface area element is given by \(dA = \sqrt{g} du_1 du_2\).

The director field \(\mathbf{n}\) can be expressed in the local basis \(\{\mathbf{Y}_1, \mathbf{Y}_2, \hat{\mathbf{N}}\}\) as:

\[
\mathbf{n} = n_i \mathbf{Y}_i + \cos \theta \hat{\mathbf{N}}, \tag{10}
\]

where the director components \(n_i, i = 1, 2\) and the tilt angle \(\theta\) are functions of the surface coordinates \(u_1, u_2\) (see Fig. 1).

The unit length of the director field yields the constraint:

\[
g_{ij} n_i n_j - \sin^2 \theta = 0. \tag{11}
\]

The three–dimensional gradient operator is given by

\[
\nabla = g^{ij} \mathbf{Y}_i \partial_j + \hat{\mathbf{N}} \partial_N, \tag{12}
\]

where \(g^{ij} \mathbf{Y}_i \partial_j\) describes the components of the gradient operator on the surface. To evaluate Eq. (9), we need to evaluate the curl and the divergence of \(\mathbf{n}\). The curl of \(\mathbf{n}\) is calculated as

\[
\nabla \times \mathbf{n} = \frac{\epsilon_{3ij}}{\sqrt{g}} \left[ (g_{ik} \partial_j n_k + g_{il} n_k \Gamma_{jk}^l) \hat{\mathbf{N}} - (2n_k L_{jk} + \partial_j \cos \theta) \mathbf{Y}_i \right], \tag{13}
\]

where \(\epsilon_{ijk}\) is the antisymmetric Levi–Civita tensor. Using Eqs. (10) and (13) we obtain the twist of the director,

\[
\nabla \cdot \mathbf{n} = \partial_j n_j + n_l \Gamma_{jl}^j - \cos \theta L_{jl} g^{ij},
\]

\[
= \partial_j n_j + n_l \Gamma_{jl}^j, \tag{15}
\]

where we have used the fact that \(H = \frac{1}{2} g^{ij} L_{ij} = 0\) for a twisted ribbon Using Eqs. (9), (13), (14), (15), the free energy Eq. (11) is given by,

\[
F = \frac{K}{2} \int \left\{ (\partial_j n_j + n_l \Gamma_{jl}^j)^2 \right. \left. - 2q \frac{\epsilon_{3ij}}{\sqrt{g}} \left[ \cos \theta (g_{ik} \partial_j n_k + g_{il} n_k \Gamma_{jk}^l) \right. \right. \left. \right. \right.
\]

\[
- (2n_k n_l g_{ik} L_{jk} + g_{il} n_k \partial_j \cos \theta) \left. \right] \hat{\mathbf{N}} - (2n_k n_l g_{ik} L_{jk} + g_{il} n_k \partial_j \cos \theta) \mathbf{Y}_i \right)^2 + q^2 \right\} \sqrt{g} du_1 du_2
\]

\[
+ \frac{C}{2} \int \sin^2 \theta \sqrt{g} du_1 du_2 + \frac{L}{g} \int \sqrt{g} du_1 du_2 + \gamma \oint dl.
\]

As noted in Ref. [13], the term proportional to \(q\) in the equation above is identical in form (up to a line integral that can be absorbed into the edge energy term proportional to \(\gamma\)) to the Helfrich–Prost term [17] first introduced to model chirality in lipid membranes.
B. Sm-

The position vector of a twisted ribbon (Fig. 2) of radius \( R \) is given by

\[
\mathbf{Y} = \{ \rho \cos \phi, \rho \sin \phi, b \phi \},
\]

where \(|\rho| \leq R\) and \(0 \leq \phi \leq 2n\pi\), and \(n\) is the winding number. The pitch of the twisted ribbon is given by \(2\pi|b|\), and the sign of \(b\) determines the handedness of the ribbon. Here we focus on a right-handed ribbon with \(b > 0\) without any loss of generality.

Defining \(u_1 \equiv \rho\) and \(u_2 \equiv \phi\), the tangent vectors and the normal vector of the surface are given by

\[
\mathbf{Y}_1 = \partial_\rho \mathbf{Y} = \{ \cos \phi, \sin \phi, 0 \}, \\
\mathbf{Y}_2 = \partial_\phi \mathbf{Y} = \{- \rho \sin \phi, \rho \cos \phi, b \}, \\
\mathbf{N} = \frac{1}{\sqrt{g}} \{ b \sin \phi, -b \cos \phi, \rho \}.
\]

Using Eq. (18) in Eq. (7) we find:

\[
\begin{align*}
\mathbf{Y}_1 &= \mathbf{Y}(\rho) = \{ \rho \cos \phi, \rho \sin \phi, b \phi \}, \\
\mathbf{Y}_2 &= \partial_{\theta} \mathbf{Y} = \{ -\rho \sin \phi, \rho \cos \phi, b \phi \}, \\
\mathbf{N} &= \frac{1}{\sqrt{g}} \{ b \sin \phi, -b \cos \phi, \rho \}.
\end{align*}
\]

FIG. 2: A twisted ribbon with radius \( R \) showing the director field determined by the solution of the Euler–Lagrange equation, Eq. (22). The figure shows a length of the ribbon equal to 0.75 times the pitch.

The pitch of the twisted ribbon is given by \(\Gamma = b \), and this can be verified explicitly using Eq. (15). Further, we assume that the director exhibits azimuthal symmetry. Furthermore we assume that the director is tilted parallel to the edge of the ribbon. The director field \(\mathbf{n}\) is then given by

\[
\mathbf{n} = \left\{ 0, \frac{\sin \theta(\rho)}{\sqrt{g}}, \cos \theta(\rho) \right\},
\]

where we have used the unit length constraint, Eq. (11).

As we will ultimately carry out a mean–field analysis of the free energy, we assume that the director field exhibits azimuthal symmetry. Furthermore we assume that the director is tilted parallel to the edge of the ribbon. The director field \(\mathbf{n}\) is then given by

\[
\mathbf{n} = \left\{ 0, \frac{\sin \theta(\rho)}{\sqrt{g}}, \cos \theta(\rho) \right\},
\]

where we have used the unit length constraint, Eq. (11). Note that the director field of Eq. (20) has zero splay; this can be verified explicitly using Eq. (15).

Within the single Frank constant approximation we have one penetration length given by \(\lambda_0 \equiv (\rho^2 b^2)^{1/2}\). The thickness of the membrane is included in the elastic moduli \(K\) and \(C\). Inserting Eqs. (18), (19), and (20) into Eq. (16) we find the following expression of the free energy:

\[
F = \int \frac{1}{2} \left[ K \left( \frac{d\theta}{d\rho} - q \right)^2 + K \left( \frac{\rho}{g} \sin 2\theta + \frac{4b}{g} \sin^2 \theta \right) \right. \\
\times \left( \frac{d\theta}{d\rho} - q \right) + K \left( g + 2b^2 \right) \left( \frac{1}{g} \sin \theta \right)^2 \\
+ C \sin^2 \theta - 2k \left( \frac{\rho^2}{g^2} \right) \sqrt{\rho} d\rho d\phi + \gamma \int \sqrt{R^2 + b^2} d\phi.
\]

The boundary conditions are given by:

\[
\begin{align*}
\theta(0) &= 0, \\
2(R^2 + b^2) \left( \frac{d\theta(\rho)}{d\rho} \right)_{\rho=R} - q + \rho \sin 2\theta(R) + 4b \sin^2 \theta(R) &= 0.
\end{align*}
\]

The EL equation and boundary conditions derived in Ref. [4] for a semi–infinite smectic layer (Fig. 3) with a
with the director component $n_2$ given by Eq. (20). Finally, the saddle–splay free energy density, Eq. (25) is given by:

$$f_{24} = \frac{K_{24}}{2g^2} \left( -2b^2 \cos^2 \theta + 2 \sin \theta \left( b^2 \sin \theta + \rho g \cos \theta \frac{\partial \theta}{\partial \rho} \right) \right. \left. -b \left( 2b \cos 2\theta \frac{\partial \theta}{\partial \rho} - \rho \sin 2\theta \right) \right).$$

(29)

In the limit of zero tilt angle (i.e., $\mathbf{n} = \mathbf{N}$), Eq. (29) reduces to the term proportional to $\bar{k}$ in Eq. (21) if we replace $K_{24}$ by $\bar{k}$. The EL equation including the saddle–splay term in place of the Gaussian curvature is given by:

$$-2g \left( \rho \frac{\partial \theta}{\partial \rho} + g \frac{\partial^2 \theta}{\partial \rho^2} \right) + 4\rho (qb^2 + b + q\rho^2) \sin^2 \theta + \left[ \frac{\rho^4}{\lambda^2} + \left( 2b^2 (\frac{b}{\lambda} - 2q) + 1 \right) \rho^2 \right.$$

$$\left. + b^2 \left( \frac{b^2}{\lambda^2} - 4qb + 3 \frac{K_{24}}{\lambda} + 3 \right) \right] \sin 2\theta = 0,$$

(30)

with the boundary condition at the edge $\rho = R$:

$$-2 \left( qR^2 + b(qb - 1) \right) - 2b \left( \frac{K_{24}}{\lambda} + 1 \right) \cos 2\theta + \left( \frac{K_{24}}{\lambda} + 1 \right) R \sin 2\theta + 2(R^2 + b^2) \frac{\partial \theta}{\partial \rho} \bigg|_{\rho = R} = 0.$$

(31)

### III. RESULTS

We now explore the results of solving the EL equations and their respective boundary conditions for the two models of the twisted ribbon: with the Gaussian curvature term (Eqs. (22)–(24) and the saddle–splay energy (Eqs. (30)–(31)). We ignore any change in the membrane thickness due to the tilt of the director and assume a common value of the Gaussian modulus $\bar{k}$ and the saddle–splay modulus $K_{24}$ in comparing the two models. For a given value of these parameters and $\gamma$, the edge energy, we determine, using a downhill–simplex algorithm, the values of the radius $R$ and pitch $b$ which minimize the free energy of the ribbon. We then compare the free energy per unit area of the twisted ribbon with the corresponding energy density of a semi–infinite Sm-A* membrane [3], where as in the case of the ribbon, the director is tilted parallel to the edge of the membrane (Fig. 3). We determine the phase boundary between the two structures using a bisection algorithm. The area $A_r$ of a twisted ribbon is given by

$$A_r = \int \sqrt{\gamma} \, d\phi \, d\theta = 2\pi \int_{R}^{R} \sqrt{\rho^2 + b^2} \, d\rho$$

$$= 2\pi b^2 \left[ \frac{R}{b} \sqrt{1 + \left( \frac{R}{b} \right)^2} + \sinh^{-1} \left( \frac{R}{b} \right) \right].$$

(32)
The energy per unit area of the semi–infinite membrane is given simply by \( q^2 / 2 \) as director tilting occurs only in a small region near the edge, and thus in Eq. [5] the contributions of twist and bend deformations to the mean free energy density are negligible.

We have considered both positive and negative values of the moduli \( \tilde{k} \) and \( K_{24} \). We find that negative values of these quantities lead to stable ribbons with ratios of pitch to radius of order 35 or greater, significantly larger than what is measured experimentally [9]. On the other hand, positive values of the moduli lead to stable ribbons with ratios of pitch to radius of order 5, in good agreement with experiment. Positive values of these moduli are not typically measured in lipid monolayers or bilayers [18]; however, there is no reason to exclude this possibility on physical grounds and the fluid system may be very different from systems composed of amphiphilic molecules. Positive moduli lead to saddle–splay and Gaussian curvature energies which are negative for a twisted ribbon. Thus, to stabilize the free energy we have added a higher–order curvature term proportional to \( K_2 \) [19, 20]. The coupling of this term to the free energy can be chosen as small as 0.01 in dimensionless units to guarantee stability for the range of \( K_{24} \) and \( \tilde{k} \) values we have studied.

Our main results are displayed in Figs. 4–6, where we present the phase diagram for semi–infinite membranes and twisted ribbons, and values of the tilt angle, pitch and width of the ribbon as functions of dimensionless variables \( \tilde{K}_{24} \equiv K_{24} / k_B T \) and \( \tilde{\gamma} \equiv 2 \lambda / k_B T \), as well as physical units obtained by using the value of \( K \) measured in [6] and \( \lambda \) measured in [8]. Our results were obtained for \( q \lambda_1 = 0.71 \), corresponding to the values of these parameters measured experimentally in Ref. [8]. We find a first order phase transition between ribbons and semi–infinite membranes (Fig. 4) as the edge energy \( \gamma \) (proportional to the depletant concentration) is varied. Furthermore, we see that even though there is a finite tilt of the molecules throughout the layer (see Fig. 5c) which should in principal distinguish between the saddle–splay and Gaussian curvature models, there is no significant difference between the calculated phase boundaries for the two models.

The dashed line in Fig. 4 is not a phase boundary; rather it is the second–order phase transition line between semi–infinite membranes and finite–sized disks calculated in a model [8] which excluded the possibility of twisted ribbons. The present calculation demonstrates that ribbons are of lower free energy than the finite–sized disks and the first–order phase transition from semi–infinite membranes to ribbons preempts the transition to finite–sized disks as \( \gamma \) is reduced, in agreement with experimental observations [8]. An examination of the various contributions to the free energy indicates that it is the reduction in the chiral energy density \(-qK_n \cdot (\nabla \times n)\) that drives the transition to the ribbon state. If \( q \), the measure of chirality, is set equal to zero, ribbons are never the lowest free energy structure.

The upward slope of the phase boundary in Fig. 4 indicates that as \( \tilde{K}_{24} \) increases the ribbon is energetically more favorable than the semi–infinite membrane. This tendency arises because increasing \( \tilde{K}_{24} \) makes the saddle–splay energy (or equivalently the Gaussian curvature energy) more negative, thus making the ribbon more favorable. This effect outweighs two factors making ribbons less favorable as \( \tilde{K}_{24} \) increases, namely, the bend energy increases and there is less twist penetration at the edge. The increase in bend energy can be inferred from Fig. 6c where the ribbon pitch \( b \) is plotted as a function of \( \tilde{K}_{24} \) for fixed \( \tilde{\gamma} \). Recalling (see the end of Sec. III) that the limit \( b \to \infty \) corresponds to a semi–infinite membrane (where the bend deformation vanishes) while the opposite limit \( b \to 0 \) corresponds to a disk of radius \( R \) where the director field exhibits bend [8]. Fig. 6c indicates that the bend energy increases with increasing \( \tilde{K}_{24} \). The decrease in twist penetrations as \( \tilde{K}_{24} \) increases can be seen from Fig. 5a where the tilt angle \( \theta_0 \equiv \theta(R) \) at the edge of the ribbon is plotted as a function of \( \tilde{K}_{24} \).

While Fig. 4 is in qualitative agreement with experiment, namely, that a first order transition is observed between semi–infinite membranes and twisted ribbons, the predicted line tension at the phase boundary, \( \gamma \sim 10 k_B T / \mu m \) is an order of magnitude lower than the value measured in experiments [8]. This discrepancy persists even when one accounts for the fact that the experiments measure an effective line tension, i.e., including the net reduction of the free energy near the edge due to twist penetration.

The tilt angle \( \theta_0 \equiv \theta(R) \) at the edge of the ribbon for
FIG. 5: (a) The value of the tilt angle $\theta_0 \equiv \theta(R)$ at the edge of the ribbon as a function of $\tilde{K}_{24}$ for $\tilde{\gamma} = 0.269$, corresponding to a point slightly below the first–order phase boundary shown in Fig. 4. The black and gray curves correspond to the Gaussian curvature and saddle–splay models respectively. The values of $\theta_0$ shown are all less than the value found for the semi–infinite membrane $\text{[4]}$; (b) $\theta_0$ as a function of $\tilde{\gamma}$ for $\tilde{K}_{24} = 0.15$, as the phase boundary is approached from below. The vertical dashed lines denote from left to right the first–order phase transition from twisted ribbons to semi–infinite membranes for the Gaussian curvature and saddle splay models. To the right of these lines the ribbon is metastable; this is indicated by the dashed nature of the $\theta_0$ curves. (c) The tilt angle $\theta(\rho)$ for the saddle–splay model with $\tilde{K}_{24} = 0.15$ as a function of $\rho$ in units of $\lambda_t$ (lower axis) and physical units (top axis) corresponding from top to bottom to the parameters: $\tilde{\gamma} = 0.25$, ($R = 2.566\lambda_t$, $b = 2.877\lambda_t$); $\tilde{\gamma} = 0.26$, ($R = 2.739\lambda_t$, $b = 3.381\lambda_t$); $\tilde{\gamma} = 0.27$, ($R = 2.965\lambda_t$, $b = 3.899\lambda_t$); and $\tilde{\gamma} = 0.28187$, ($R = 3.385\lambda_t$, $b = 4.707\lambda_t$). The lowest curve ($\tilde{\gamma} = 0.28187$) corresponds to the phase boundary.

both the Gaussian curvature and saddle–splay models is shown as a function of both $\tilde{K}_{24}$ and the edge energy $\gamma$ in Figs. 5a and 5b respectively. From Fig. 5a we see that as with the phase boundary shown in Fig. 4 there is negligible difference between the results for the two models. The vertical dashed lines in Fig. 5b correspond to the first–order phase transition boundaries shown in Fig. 4 for the saddle–splay and Gaussian curvature models. To the right of these lines the ribbon is metastable which we indicate by the dashed plotting of $\theta_0$. For semi–infinite membranes $\text{[4]}$, $\theta_0 = -\arcsin(q\lambda_t) = 0.79$ for $q\lambda_t = 0.71$, independent of $\tilde{\gamma}$. This value exceeds $\theta_0$ for the twisted ribbon in both the saddle–splay and Gaussian curvature models for all values of $\tilde{\gamma}$ and $\tilde{K}_{24}$, in agreement with experiment $\text{[4]}$. In Fig. 5c we show examples of the tilt angle profile $\theta(\rho)$ for the saddle–splay model with $\tilde{K}_{24} = 0.15$ for a range of $\tilde{\gamma}$ slightly below and on the first–order phase boundary of Fig. 4.

The pitch $2\pi b$ and width $2R$ of the ribbon are shown as functions of $\tilde{\gamma}$ and $\tilde{K}_{24}$ in Figs. 6a–d. In Figs. 6a and 6b we see that there is some difference between the Gaussian curvature and saddle–splay models for the dependence of the pitch on $\tilde{\gamma}$; we have no simple physical reason for this difference. Fig. 6e shows the geodesic curvature $\kappa_g$ $\text{[12]}$ of the edge of the ribbon:

$$\kappa_g = \frac{R}{R^2 + b^2}$$

as a function of $\tilde{\gamma}$ in the neighborhood of the first–order transition. For both the Gaussian curvature and saddle–splay models the geodesic curvature decreases as the phase transition is approached from below, while Fig. 5b shows that the $\theta_0$ increases. This result is consistent with experimental retardance data which shows that lower
FIG. 6: The (a) pitch $2\pi b$ and (b) width $2R$ of the ribbon in units of $\lambda_t$ (left vertical axis) and $\mu m$ (right vertical axis) as functions of $\tilde{\gamma}$ at $\tilde{K}_{24} = 0.15$. Black and gray curves correspond to the Gaussian curvature and saddle–splay models respectively. The gray vertical dashed lines denote from left to right the first–order phase transition from ribbons to semi–infinite membranes for the Gaussian curvature and saddle–splay models, respectively. To the right of these lines the ribbon is metastable; this is indicated by the dashed nature of the curves. In (c) and (d) respectively the pitch and width are shown as functions of $\tilde{K}_{24}$ close to the phase boundary at $\tilde{\gamma} = 0.269$. Again, black and gray curves correspond to the Gaussian curvature and saddle–splay models respectively. The geodesic curvature, Eq. (33), as a function of $\tilde{\gamma}$ is shown in (e).

curvature of the edge in general leads to a higher tilt angle at the edge.

IV. CONCLUSION

In this paper, we have developed a theoretical model for the Sm-A* twisted ribbons observed in assemblies of fd viruses condensed by depletion forces. The depletion
interaction is modeled by an edge energy (line tension), assumed to be proportional to the depletant polymer in solution. We have considered two variants of this model, one with the conventional Helfrich Gaussian curvature term, and a second with saddle–splay energy. Both models yield a first–order phase transition between ribbons and semi–infinite flat membranes as the edge energy is varied. The phase transition line and tilt angle profile are found to be nearly identical for the two models; the pitch of the ribbon, however, does show some differences. Our model yields good qualitative agreement with experimental observations, namely, (1) the existence of a first–order phase transition between ribbons and semi–infinite membranes, preempting a transition to finite–sized disks; (2) the dependence of the tilt angle at the edge of the ribbon on the curvature of the edge; (3) the decrease in the tilt angle at the edge of the membrane as the system undergoes the first–order transition from the semi–infinite membrane to the ribbon; (4) the order of magnitude of the pitch to width ratio of the ribbon. While the phase diagram is in qualitative agreement with experiment the predicted line tension on the phase boundary is an order of magnitude lower than that measured experimentally. Also, as we noted in Sec. III, obtaining the correct order of magnitude of the pitch to width ratio requires a positive value of the Gaussian curvature or saddle–splay modulus which favors negative Gaussian curvature. These moduli have not been directly measured in the fd system nor have microscopic models been developed for nonamphiphilic molecules.
