We have considered 53 Type Ia supernovae (SNe Ia) observed by the Swift X-Ray Telescope. None of the SNe Ia are individually detected at any time or in stacked images. Using these data and assuming that the SNe Ia are a homogeneous class of objects, we have calculated upper limits to the X-ray luminosity (0.2–10 keV) and mass-loss rate of $L_{0.2-10} < 1.7 \times 10^{38}$ erg s$^{-1}$ and $M < 1.1 \times 10^{-6}$ $M_\odot$ yr$^{-1}$ $(v_w)/(10 \text{ km s}^{-1})$, respectively. The results exclude massive or evolved stars as the companion objects in SN Ia progenitor systems, but allow the possibility of main sequence or small stars, along with double degenerate systems consisting of two white dwarfs, consistent with results obtained at other wavelengths (e.g., UV, radio) in other studies.

Key words: circumstellar matter – supernovae: general – X-rays: general – X-rays: ISM

1. INTRODUCTION

Type Ia supernovae (SNe Ia) are generally considered to be thermonuclear explosions of white dwarfs (WDs; e.g., Hillebrandt & Niemeyer 2000). Such explosions can occur if the WD reaches or exceeds the Chandrasekhar limit, although some models suggest that the explosion can occur below the Chandrasekhar limit (van Kerkwijk et al. 2010 for example). There are two main classes of models currently considered to be possible progenitor systems for SNe Ia (Hillebrandt & Niemeyer 2000): (1) one WD accretes mass from a binary companion until it exceeds the Chandrasekhar limit (Whelen & Iben 1973; Iben & Tutukov 1984; Nomoto 1982; single-degenerate (SD) model) and (2) two WDs merge (Webbink 1984; Iben & Tutukov 1984; double-degenerate (DD) model). In the SD model, the companion star emits a stellar wind that populates the circumstellar region with matter, or the star fills the Roche lobe (Branch 1998). The SN shock would run into this circumstellar matter and heat it to high enough temperatures ($\sim 10^5$–$10^7$ K) so that it produces thermal X-rays, depending on the fraction accumulated by the WD (Chevalier 1990). For the DD model both stars in the binary system have long ago ceased producing significant wind, and therefore the circumstellar region will be devoid of matter (Branch 1998). Hence, no thermal X-ray emission is expected from shock interaction.

Various observations and studies have been made in an attempt to determine which of these models is correct. In the SD model, there are several methods of mass transfer. One is the so-called symbiotic binary system, where a fraction of the wind from a binary companion is accreted by the WD until it reaches the Chandrasekhar limit (Panagia et al. 2006). Panagia et al. (2006) have put constraints on this possibility by analyzing radio observations of a sizable sample of SNe Ia. See below for more discussion of their results. Another possible scenario is that of a massive binary in Roche lobe overflow with material again being accreted onto the WD (Panagia et al. 2006). Panagia et al. (2006) placed a limit on this, stating that such a method would be required to be 60%–70% efficient to avoid detectable circumstellar matter (CSM). These limits rely on the conclusions of Nomoto (1984) regarding the conditions of accretion to allow a WD to become an SN Ia.

A Very Large Array (VLA) observation of SN 1986G looking for early radio emission resulting from the interaction of the SN shock with the wind from a red giant companion detected no such emission at 2 cm and 6 cm. The 3$\sigma$ upper limits of 0.7 and 1.0 mJy, respectively, are in conflict with those expected from the symbiotic case (Eck et al. 1995), although they point out that this was a “peculiar” SN Ia. Panagia et al. (2006) conducted a radio survey of 27 SNe Ia and detected no radio emission (with a highest radio luminosity upper limit of $4.2 \times 10^{26}$ erg s$^{-1}$), therefore concluding that these systems have low CSM densities. They explicitly argue against the SD model for a massive companion, but state that their results do allow for a relatively low mass companion. They also provide 2$\sigma$ upper limits for the mass-loss rate for the system as $3 \times 10^{-8}$ $M_\odot$ yr$^{-1}$, the lowest upper limits published to date.

Schlegel & Petre (1993) have observed SN 1992A using ROSAT searching for X-rays. They establish an X-ray luminosity upper limit of $3 \times 10^{38}$ erg s$^{-1}$ and a mass-loss rate upper limit of a few $10^{-6}$ $M_\odot$ yr$^{-1}$ (Schlegel & Petre 1993). Hughes et al. (2007) used the Chandra X-ray telescope to observe four SNe Ia. For two of the SNe Ia they observed (SN 2002bo and SN 2005ke), they detected no X-rays and obtained an upper limit of $2 \times 10^{-9}$ $M_\odot$ yr$^{-1}$ for 2002bo. For the other two (SN 2002ic and SN 2005gj), they find upper limits about four times lower than would be expected for circumstellar interaction and propose a mixing scenario to increase X-ray absorption.

Immler et al. (2006) have determined relatively deep upper limits on X-ray emission from SNe Ia using the Swift X-Ray Telescope (XRT). They examined SN 2005ke, but found inconclusive evidence for X-ray emission. They determine upper limits of luminosity of $(2 \pm 1) \times 10^{38}$ erg s$^{-1}$ and mass-loss rate of $3 \times 10^{-9}$ $M_\odot$ yr$^{-1}$ $(v_w)/(10 \text{ km s}^{-1})$, the lowest upper limits published to date from X-ray observations.

Hancock et al. (2011) have stacked VLA radio data from 46 observations of nearby SNe Ia to create a deep image and obtained a radio luminosity upper limit of $1.2 \times 10^{25}$ erg s$^{-1}$ Hz$^{-1}$ at 5 GHz and a mass-loss rate upper limit for the progenitor system of $1.3 \times 10^{-7}$ $M_\odot$ yr$^{-1}$.

Our goal in this Letter is to add to and expand on the previous X-ray studies. Of all past and present X-ray observatories, Swift/XRT has observed the largest sample of SNe in X-rays,
with unprecedented early observations starting just days after outburst. We use data from XRT to determine an upper limit on X-ray luminosity from more than 50 SNe Ia, adding to the growing consensus regarding the progenitor systems of these events.

2. DATA

XRT (Burrows 2005) on board the Swift telescope (Gehrels et al. 2004) has observed more than 170 SNe to date. Of these, 55 are SNe Ia (at the time of writing). In order to further narrow this sample down to increase the chances of detecting X-rays from the SN, we applied the following conditions for selection:

1. young: observations begin within 100 days of SN discovery;
2. nearby: distance to SN within 130 Mpc (using previously determined distances from NED and references therein); and
3. contamination with nearby X-ray source: separation of SN position from nearby X-ray source > 24′ (corresponding to the XRT’s 90% encircled energy width).

These conditions lead to the selection of 53 of the SNe Ia that have been observed by the XRT in our calculations. They are listed in Table 1 (which is published in its entirety in the online journal), along with their individual luminosity upper limits. Some of these are relatively high due to contamination from the galactic nucleus. All X-ray data used are in the 0.2–10 keV energy band.

3. METHOD

We co-added all individual observations (ObsIDs) using the ximage software package (version 4.4.1) to produce a sky image for each SN. We then used the ximage analysis package to determine a 3σ upper limit on count rate for each SN image, using a 5 pixel radius corresponding to point-spread function encircled energy radius of roughly 90% centered on the optical position of the respective SN and a background region in a source-free region of the image. These count rates were corrected for 100% encircled energy radius and were converted to an unabsorbed flux using the online pimms tool (version 4.3) using the appropriate column density for the host galaxy (Dickey & Lockman 1990) and assuming a 10 keV thermal bremsstrahlung plasma (Fransson et al. 1996). By making the assumption that all SNe Ia result from the same type of progenitor system, we can follow Panagia et al. (2006) to add these 53 upper limits using the equation \( \sigma^2 = (\Sigma \sigma_i^2)^{-1} \), where \( \sigma_i \) is the upper limit from the \( i \)th SN and we sum over all of the SNe in our sample.

In order to determine the rate of material lost by SN Ia systems via the winds of a possible companion star, we make several assumptions with respect to model and parameters. We assume spherically symmetric stellar wind, and we calculate the mass-loss rate via (Chevalier & Fransson 2003; Immler et al. 2006)

\[
L = \frac{1}{4 \pi m_\odot} \Lambda(T) \left( \frac{M}{M_\odot} \right)^2 (v_w t)^{-1},
\]

where \( L_{\odot} \) is the X-ray luminosity determined from the data; \( m \) is the average particle mass of 1.8 \( \times \) \( 10^{-27} \) kg for an H+He plasma with solar composition; \( t \) is the time after outburst determined by weighted average; \( v_w \) is the wind speed assumed to be 10,000 km s\(^{-1}\); \( T_e \) is the electron temperature (\( T_e = 1.36 \times 10^8 (n - 2)^{-2} (v_w/10^8 \text{ km s}^{-1})^2 \) K) and \( g_{\text{ff}} \) is the free–free Gaunt factor. \( n \) is the power-law index of the SN ejecta: \( \rho \propto r^{-\alpha} \) and ranges from 7 to 10. Here we assume it to be 8. The reverse shock is in equipartition unless \( T > 5 \times 10^8 \) K (Chevalier & Fransson 2003).

Using the same images, all sources were removed with the detect/remove command in ximage. These “cleaned” images were then analyzed in the same way as above, and results were similar.

4. RESULTS

None of the 53 SNe Ia are detected at any time or in stacked images. For the individual SNe, we find the X-ray luminosity 3σ upper limits range from 2.7 \( \times \) \( 10^{38} \) erg s\(^{-1}\) to 2.3 \( \times \) \( 10^{41} \) erg s\(^{-1}\) (0.2–10 keV). The mass-loss rate upper limits range from 7.5 \( \times \) \( 10^{-5} \) to 4.0 \( \times \) \( 10^{-6} \) \( M_\odot \) yr\(^{-1}\) \( \times (v_w)/(10 \text{ km s}^{-1}) \). By combining the upper limits for the individual SNe, we obtain a 3σ upper limit on the X-ray luminosity of 1.7 \( \times \) \( 10^{38} \) erg s\(^{-1}\) and a 3σ upper limit on the mass-loss rate of 1.1 \( \times \) \( 10^{-6} \) \( M_\odot \) yr\(^{-1}\) \( \times (v_w)/(10 \text{ km s}^{-1}) \). All luminosities are reported in the 0.2–10 keV energy band.

5. DISCUSSION

In this Letter, we present the deepest flux limits and upper limits on the mass-loss rates of SN Ia companion objects obtained from X-ray observations to date. These results are combined with those obtained at radio wavelengths of other studies in Figure 1. From these mass-loss upper limits, we can make statements about the progenitor system for a generic, average SN Ia, assuming that SNe Ia form a homogeneous class of objects.

(This table is available in its entirety in a machine-readable form in the online journal. A portion is shown here for guidance regarding its form and content.)
Radio and X-ray studies of nearby core-collapse SNe have shown that the mass-loss rates of massive progenitors are well above the limit inferred in this study ($10^{-6}$–$10^{-5}$ $M_\odot$ yr$^{-1}$). Wind accretion is generally about 10% efficient (Yungelson et al. 1995). If 10% of the wind is being accreted onto the WD, that would increase the mass loss from the companion by 10% over the upper limits presented here. The result is still below the mass loss expected from a massive star, and therefore we can rule out wind from a massive star accreting onto a WD as the progenitor system for SNe Ia. We cannot rule out a main-sequence star as a companion with mass-loss rates $<10^{-7}$ $M_\odot$ yr$^{-1}$ in a wind-accretion scenario. A DD WD system is also not excluded due to the lack of CSM interaction and hence the lack of emitted X-rays. The possibility of a massive companion in Roche lobe overflow is also still permitted by these limits. Our results qualitatively support results from other wavelength regimes, such as in the radio (Panagia et al. 2006; Hancock et al. 2011) and in the UV (Brown 2011).

Our results improve on the previous lowest published upper limit derived from X-ray observations, $3 \times 10^{-6}$ $M_\odot$ yr$^{-1}$ in Roche lobe overflow is also still permitted by these limits. Our results provide further evidence that the companion stars in SNe Ia progenitor systems are not a massive star (e.g., red supergiant or post-main-sequence) in a wind-accretion scenario. Lower-mass main-sequence stars with small amounts of mass lost in stellar winds, a WD companion in DD SNe Ia systems or a massive star in Roche lobe overflow, are not excluded. It is also possible that SNe Ia do not form a homogeneous class of objects in which case there may be individual detections of X-rays from some SNe Ia.

6. SUMMARY

Using the largest sample of SNe Ia available for stacking analysis, we have generated a deep Swift/XRT X-ray image of 3.05 Ms exposure time. We determine that there is no X-ray source at the position of the stacked SNe. We calculate a 3$\sigma$ upper limit for the X-ray luminosity of $1.7 \times 10^{38}$ erg s$^{-1}$ and an upper limit on the mass-loss rate of $1.1 \times 10^{-6}$ $M_\odot$ yr$^{-1}$ from the SN progenitors. The low upper limits provide further evidence that the companion stars in SNe Ia progenitor systems are not a massive star (e.g., red supergiant or post-main-sequence) in a wind-accretion scenario. Lower-mass main-sequence stars with small amounts of mass lost in stellar winds, a WD companion in DD SNe Ia systems or a massive star in Roche lobe overflow, are not excluded. It is also possible that SNe Ia do not form a homogeneous class of objects in which case there may be individual detections of X-rays from some SNe Ia.
