(Dated: 18 February 2011)

We experimentally demonstrate coherent light scattering from an atomic Mott insulator in a two-dimensional lattice. The far-field diffraction pattern of small clouds of a few hundred atoms was imaged while simultaneously laser cooling the atoms with the probe beams. We describe the position of the diffraction peaks and the scaling of the peak parameters by a simple analytic model. In contrast to Bragg scattering, scattering from a single plane yields diffraction peaks for any incidence angle. We demonstrate the feasibility of detecting spin correlations via light scattering by artificially creating a one-dimensional antiferromagnetic order as a density wave and observing the appearance of additional diffraction peaks.

PACS numbers: 42.50.Ar, 67.85.-d, 42.25.Fx, 37.10.Jk

Ultracold atoms in optical lattices have become a useful tool to simulate static phases and the dynamical responses of quantum many-body systems [1]. Recent interest has focused on reaching sufficiently low temperatures and entropies to observe magnetically ordered quantum phases [2]. In this context, light scattering has been proposed as a new tool to detect these quantum correlations. Spin correlations could be mapped onto correlations of scattered light [3] or be detected via diffraction peaks from the additional scattering planes for spin-dependent probe light [4]. Light scattering would allow to measure the temperature of fermions in an optical lattice [5] or the density fluctuations across the superfluid-to-Mott-insulator transition [6, 7]. Since the amount of scattered light is usually very small, several proposals involve a cavity for the detection [8]. Without cavities, elastic Bragg scattering has been used to demonstrate the long range periodic order of thermal atoms in an optical lattice despite very low filling factors [9, 10]. It allowed the measurement of a change of the lattice constant from the backaction of the atoms [9, 10], their localization dynamics [11] and temperature [10]. Bragg scattering was also studied in a far-detuned one-dimensional lattice [12].

Here we show coherent light scattering from an atomic Mott insulator (MI) in a two-dimensional square lattice structure. Scattering from a 2D geometry differs significantly from usual Bragg scattering, because the momentum transfer needs to be an integer multiple of a reciprocal lattice vector only within the plane. Therefore diffraction peaks appear for any angle of the incoming beam, which is experimentally more convenient. In our setup, we use five probe beams in a molasses configuration that simultaneously laser cool the atoms. Each of these molasses beams yields distinct diffraction peaks in the far-field images. We quantitatively compared the diffraction patterns with model calculations and confirmed the coherent nature of the scattering process. We artificially prepared 1D antiferromagnetic order as a density wave and observed additional diffraction peaks, thus demonstrating the usability of light scattering for the detection of global spin correlations.

We begin by introducing a simple analytic 1D model to illustrate the underlying physics. Atoms on a 1D lattice (lattice spacing $a_{\text{lat}} = \lambda_{\text{lat}}/2$, $\lambda_{\text{lat}}$ is the lattice wavelength) are driven by an incoming light field (wavelength $\lambda$) from the $x$ direction [Fig. (a)] with wave vector $\mathbf{k}_i = k \mathbf{e}_x$, where $k = 2\pi/\lambda$ and $\mathbf{e}_x$ is the unit vector along $x$. The scattered light is detected at a point...
r, defined by the angle θ with the z-axis, such that 

\[ r = r \mathbf{e}_r = r \sin \theta \mathbf{e}_z + r \cos \theta \mathbf{e}_x. \]

The position of the i-th atom is \( \mathbf{x}_i = l \mathbf{a}_{\text{lat}} \mathbf{e}_z \) and its distance \( r_i \) to the detection point is in far-field approximation \( r_i = |r - x_i| \approx r - x_i \mathbf{e}_r. \)

In our model, each atom emits a spherical wave, which at the detection point can be written as

\[ F_i(r_i) = f \frac{e^{i k r_i}}{r_i} e^{i \delta_i} \approx f \frac{e^{i k r}}{r} e^{-i K \cdot x_i}. \] (1)

Here, \( f \) denotes the coherently scattered field amplitude, \( \delta_i = \mathbf{k} \cdot \mathbf{x}_i \) is the phase imprinted by the incoming light field, and \( K = \mathbf{k}_0 - \mathbf{k}_i \) with the wave vector \( \mathbf{k}_0 = k \mathbf{e}_r \) in the observed direction. The differential cross section \( \frac{d \sigma}{d \theta} (K) \propto |\sum e^{-ik \mathbf{x}_i}|^2 \) is obtained by summing over the field amplitudes from all \( N_x \) atoms. As a result, we obtain the angular dependence of the scattered light field, with distinct maxima when the field amplitudes of neighboring atoms interfere constructively, i.e. \( \mathbf{K} \cdot (\mathbf{x}_i - \mathbf{x}_{i+1}) = 2 \pi \cdot n \), where \( n \) is an integer that denotes the diffraction order. The height of the diffraction peak is proportional to \( N_x^2 \) whereas the peak width scales as \( 1/N_x \). The angles \( \theta_n \), under which the diffraction maxima can be observed, are given by

\[ \sin \theta_n = 1 + n \frac{\lambda}{a_{\text{lat}}}. \] (3)

The trivial case \( n = 0 \) gives the forward scattered light (\( \theta_0 = 90^\circ \)), independent of \( a_{\text{lat}} \) and \( \lambda \). For our experimental parameters (\( \lambda = 780 \text{ nm}, a_{\text{lat}} = 532 \text{ nm} \)), Eq. (3) can be additionally fulfilled only for \( n = -1 \), yielding the corresponding minus first diffraction order at \( \theta_{-1} = -27.8^\circ \) and \( 207.8^\circ \). These two out of plane scattered waves ensure the momentum conservation in the z direction. Fig. 1(b) (blue curve) shows a polar plot of \( \frac{d \sigma}{d \theta} (\theta) \), displaying the forward scattered light and the two peaks, one of which is captured by our imaging system (gray shaded region). If only every second lattice site is occupied (e.g. after removing one spin component in an antiferromagnetically ordered sample), the periodicity of the system is doubled. In this case, there are two possible diffraction orders (in the upper half plane) at \( \theta_{AFM} = 15.5^\circ \) and \( \theta_{-2} \) \( \theta_{-2} = -27.8^\circ \) [green curve in Fig. 1(b)].

In our experiment, we prepared 2D Mls of \(^{87}\text{Rb} \) atoms in an optical lattice. The atoms were confined in a single antinode of a vertical standing wave. Two pairs of horizontal laser beams provided the square lattice structure (see Ref. 13). In order to detect the atoms in the optical lattice, the lattice depth was increased to \( \sim 300 \mu \text{K} \), thereby freezing the atom distribution. The atoms where then illuminated with an optical molasses, which consisted of two pairs of retroreflected laser beams oriented along the horizontal lattice axes [see Fig. 1(c)]. A fifth molasses beam entered from the reverse direction of the imaging system (not shown in Fig. 1(c)). The molasses was red detuned with respect to the free space resonance by 45 MHz and the total scattering rate was 60 kHz. We detected the fluorescence photons with a high resolution microscope objective with half opening angle \( \alpha = 43^\circ \). The objective can be moved in the z direction by a distance \( \Delta z < 100 \mu \text{m} \) between the atom position and the focal plane within 50 ms using a piezo scanning device.

Our experimentally obtained diffraction images are shown in Fig. 2(a) for four different distances \( \Delta z \) and an illumination time of 200 ms for each image. For \( \Delta z = 0 \) we observed the in situ atom number distribution, consisting in this case of 147 atoms in a MI shell with unit occupancy and diameter of \( 6 \mu \text{m} \). For larger \( \Delta z \), we observe the build up of the far-field distribution with distinct diffraction peaks. We compared the experimental data with a numerical calculation of \( \frac{d \sigma}{d \theta} (K) \) using the actual atom distribution of the image at \( \Delta z = 0 \) [Fig. 2(b)]. For this purpose, we coherently summed over all spherical waves \( F_i(r_i) \) emitted by the atoms with phases \( \delta_i \) given by the incident driving fields. Our model assumes that all four horizontal molasses beams are diffracted independently. A spherical wave for the emission pattern is used, because the different local polarizations in the molasses result in all possible orientations of the atomic dipole. The calculated far-field distribution is in good qualitative agreement with the experimental images. Our simulation only includes the coherently scattered light, whereas the experimental data also shows a significant incoherent background.

For a more quantitative analysis, we recorded diffraction patterns of Mls for different atom numbers [Fig. 2(a)-(c)]. We evaluated cuts (angular sectors of width \( 4^\circ \))

![FIG. 2. Light scattering from a 2D MI. (a) Experimental images from the same atomic sample for four different distances \( \Delta z \) of the focal plane with respect to the atom position. The lowest image shows the in situ atom number distribution, whereas the upper image shows the far-field diffraction pattern. through the diffraction peaks and the background signal [see Fig. 3(c)] and applied an appropriate coordinate transformation in order to obtain the angular distribution \(\sigma(\theta)\), as shown in Fig. 3(d). We fitted the resulting peaks with a Gaussian (height \(A\), 1/\(\sqrt{\sigma} \) width \(w\), center position \(\theta_{-1}\), and offset fixed at the background value). The peak position, averaged over all experimental runs is \(|\theta_{-1}| = 27.4(6)\degree\), in excellent agreement with the expected value of \(|\theta_{-1}| = 27.8\degree\). This is dominated by the systematic uncertainty of ±1 μm in the determination of \(\Delta z\). The peak height scales quadratically with the atom number [Fig. 3(c)], illustrating the coherent nature of the diffraction peak. The peak width scales as \(w \propto 1/\sqrt{N}\) [Fig. 3(f)], in agreement with the result from the 1D model [Eq. 2], assuming \(N_x = \sqrt{N}\) atoms in one dimension.

There are several mechanisms that lead to a background outside the diffraction peaks. The first mechanism is the deviation from integer occupation of the lattice sites caused by density fluctuations in the system [6]. The second mechanism is the spread of the atoms in their potential wells, which reduces the peak height via the Debye-Waller factor. In our case, the dominant mechanism, however, is inelastic light scattering in the molasses configuration. We used the far-field images to extract the power scattered into the detected diffraction peaks and the power scattered into the background. In the cuts outside the diffraction peaks, we found a constant background \((\text{const} b)\), and calculated the total incoherent scattering cross section \(\sigma_t = 4\pi(\text{const} b)\), assuming an isotropic intensity distribution. The total scattering cross section from the five molasses beams can be estimated as \(\sigma_p \approx 10\sin(\theta_{-1})2\pi Aw^2\cos(\theta_{-1})\). The factor \(\cos(\theta_{-1})\) accounts for the ellipticity of the diffraction peaks due to the effective ellipticity of the atomic cloud, when viewed under the angle \(\theta_{-1}\). Fig. 3(g) shows \(\sigma_p\) and \(\sigma_b\), both scale linearly with the number of atoms. From the slopes, we find a fraction \(f_p = \sigma_p/(\sigma_b + \sigma_p) \approx 3\%\) of the power scattered into the detected peaks. Only about 20\% of the coherently scattered light is diffracted into these peaks, while the forward scattered part is not detected here.

In addition to the four diffraction peaks from the horizontal molasses beams, a fifth weaker peak is clearly visible in the center left part of the far-field images [see white circle in Fig. 3(c)]. This peak results from the diffraction of the molasses beam which is shone in from the direction of the imaging system. It shows that our single plane of a few hundred atoms in the optical lattice acts as a “mirror” for the incoming laser beam.

Finally, we demonstrated that light scattering can be used for the detection of spin correlations. As an example, we created a 1D z-Néel antiferromagnetic order along the \(x\) direction of the lattice using our recently demonstrated single-site addressing technique [14]. We sequentially flipped all atomic spins in every second row of the lattice from \(F = 1\) to \(F = 2\) before we applied a resonant laser that removed all atoms in \(F = 2\). Figs. 4(a) and (b) show the resulting fluorescence image in the focal plane together with the reconstructed atom number distribution. The corresponding experimental and theoretical diffraction patterns are displayed in Figs. 4(c) and (d). The two predicted diffraction peaks of \(-1^{\text{st}}\) and \(-2^{\text{nd}}\) order along \(x\) are clearly visible in the experimental picture, although our atomic sample consisted of only 57 atoms. We obtain the usual peak position of \(|\theta_{-1}^x| = 27.7(6)\degree\) along the \(y\) direction, whereas the two peaks along \(x\) are found at \(|\theta_{-1}^x| = 14.5(6)\degree\) and \(|\theta_{-2}^x| = 27.4(6)\degree\) [see Figs. 4(c),(f)], in good agreement with the expected val-
We prepared a 1D antiferromagnetic order, because the additional diffraction peaks that would arise for a 2D antiferromagnetic order lie outside the opening angle of our imaging system. However, the position of the diffraction peaks could be varied in a 2D geometry by changing the angle of the incident beams. An alternative is to use shorter wavelength probe light, e.g. near-resonant with the $5S - 6P$ transition at 420 nm for $^{87}\text{Rb}$.

Our results could be extended to the study of various density [6, 7] or spin [3, 4] correlations in optical lattices. Most proposals suggest weak non-destructive probing, which restricts the signal to only a few photons per atom. In our alternative approach, we projected the correlations onto the density before the detection by means of an optical molasses, which yields a signal of thousands of photons per atom. This is possible for density correlations, as e.g. the number squeezing in a MI lattices. Most proposals suggest weak non-destructive probing, which restricts the signal to only a few photons per atom. In our alternative approach, we projected the correlations onto the density before the detection by means of an optical molasses, which yields a signal of thousands of photons per atom. This is possible for density correlations, as e.g. the number squeezing in a MI
