Suppressing male spermatogenesis-associated protein 5-like gene expression reduces vitellogenin gene expression and fecundity in *Nilaparvata lugens* Stål

Lin-Quan Ge¹, Ting Xia¹, Bo Huang¹, Qi-Sheng Song², Hong-Wei Zhang², David Stanley³, Guo-Qing Yang¹ & Jin-Cai Wu¹

In our previous study with the brown planthopper (BPH), *Nilaparvata lugens*, triazophos (tzp) treatments led to substantial up-regulation of a male spermatogenesis-associated protein 5-like gene (*NlSPATA5*) compared to untreated controls. Mating with tzp-treated males significantly increased fecundity (as numbers of eggs laid), relative to females mated with untreated males. Because SPATA5 acts in mammalian sperm development and is expressed in testes, we posed the hypothesis that *NlSPATA5* occurs in BPH seminal fluid and it operates in fecundity via mating. We tested the hypothesis by investigating the influence of suppressing *NlSPATA5* expression in BPH males on fecundity. Reduced expression of *NlSPATA5* led to decreased male accessory gland protein content and reproductive system development compared to controls. These changes in males led to prolonged pre-oviposition periods and decreased fecundity in females. For both genders, we recorded no difference in the body weight, oviposition periods, and longevity compared to controls. *NlSPATA5* suppression in males also led to decreased fat body and ovarian protein content, yeast-like symbionts abundance and ovarian development as well as vitellogenin gene expression in their mating partners. We infer that increased *NlSPATA5* expression may be one molecular mechanism of tzp-driven reproduction and population increases in BPH.

The brown planthopper (BPH), *Nilaparvata lugens* (Stål) is a serious pest of rice crops in Asia and Australia¹ and a classic example of an insecticide-induced resurgent pest². Previous studies have demonstrated that insecticide treatments enhanced BPH male accessory gland (MAG) protein content⁴. Compared to crossing with untreated males, females mating with insecticide-treated males led to increased fecundity, registered as numbers of eggs laid⁵. The effects of insecticides on BPH reproduction appear to operate through a spermatogenesis-associated protein 5-like (*NlSPATA5*) gene because it was up-regulated after triazophos (tzp)-treatment. However, a direct link between *NlSPATA5* up-regulation and female reproduction has not been investigated⁴. Nonetheless, because of its broad importance in animals, it has become a BPH gene of interest.

In insects, MAG proteins are essential components of seminal fluids that act in influencing post-mating changes in female behavior, such as reduced sexual receptivity⁶, increased oviposition⁷ and increased sexual refractory periods⁸. MAG proteins act in sperm transport and storage, and because they also include antimicrobial peptides, they provide prophylactic protection of the female reproductive tract⁹. Insect mating systems

¹School of Plant Protection, Yangzhou University, Yangzhou 225009, P.R. are evolved and tremendously varied traits. For a single example, MAG proteins do not induce refractoriness in all species. MAG proteins also influence post-mating female physiology, stimulating oogenesis, ovulation and oviposition. The idea that males can influence their sexual partners via constituents of their seminal fluids has helped to understand the mating systems of many animal species and may have practical relevance for insect pest management technologies.

Spermatogenesis-associated proteins (SPATAs) were discovered in research designed to identify new spermatogenesis-associated genes. This work with a human testis cDNA library yielded a protein-encoding gene first called PD1 and later renamed spata2, later shown to operate in spermatogenesis and pancreatic islets. Several spatas, and RNA splicing variants, have been identified, most of which act in diverse areas of testicular biology. For one example, SPATA6 is thought to act in testicular germ cell tumors in a human embryonic carcinoma cell line. SPATA proteins also occur in insects, identified among a range of genes associated with spermatogenesis in Drosophila as well as human genomes. In a similar vein, treating BPH with the organophosphate, tzp, led to increased expression of several proteins, including a SPATA5-like protein. This finding led to hypotheses about the possible biological significance of SPATA5 in BPH.

We investigated the possibility that a single male gene product, NISPATA5, influences parameters of female reproductive biology. If this idea were strongly supported, the gene encoding NISPATA5 could potentially serve as a target for RNAi based control of insect pests in transgenic plants. We posed this concept as the hypothesis that NISPATA5 occurs in BPH seminal fluid and it operates in fecundity via mating. If this idea were strongly supported in the future research, suppressing NISPATA5 expression will influence the post-mating behavior and physiology of female partners, which would reduce BPH fitness in agroecosystems. Here we report on the outcomes of experiments designed to test our hypothesis.

Results
Expression analysis of NISPATA5. Although it appears that NISPATA5 expression declined with age in adult males, statistical analysis confirmed the abundances of mRNA encoding NISPATA5 remained at the same level from days 1 to 7 following adult male emergence ($F = 2.3$, $df = 6, 20, P = 0.10$; Fig. 1A). We used cDNA prepared from unmated females as negative controls in which we detected no NISPATA5 transcripts.

Analysis of abundances of mRNA encoding NISPATA5 in untreated controls, dsGFP-treated controls and NISPATA5-treated males confirmed that dietary dsNISPATA5 treatments significantly down-regulated NISPATA5 expression in adult males for the first seven days of adulthood ($F = 374.9$, $df = 2, 42, P = 0.0001$) (Fig. 1B). To evaluate the effect of dietary dsRNA on NISPATA5 mRNA abundances, the expression value of untreated controls was converted to 1. Dietary dsNISPATA5 treatments led to reduced NISPATA5 expression in males, by about 41~67% compared to untreated controls, and by approximately 46~68% compared to dsGFP control over the seven day period. The average of NISPATA5 expression was not significantly influenced by interaction effect between DPE and dsRNA treatments ($F = 1.6$, $df = 12, 42, P = 0.13$).

The influence of dietary dsNISPATA5. Dietary dsNISPATA5 treatments led to significantly reduced abundances of mRNA encoding NISPATA5 in males at day 2 post-emergence (2 DPE) as just shown (Fig. 2A)

![Figure 1](image-url)
$F = 54.4$, df = 2, 8, $P = 0.0001$), down by about 56% compared to untreated controls and by approximately 58% compared to dsGFP controls (Fig. 2A). Dietary dsNISPATA5 treatments led to significantly decreased soluble MAGs protein contents at 2 DPE ($F = 106.4$, df = 2, 8, $P = 0.0001$), down by circa 30% (from 4.27 μg/mg

**Figure 2. Influence of dietary dsNISPATA5.** Panel (A) the histogram bars show mean relative gene expression ± S.E (n = three independent biological replicates) at 2 DPE. Panel (B) the histogram bars show mean MAG protein content (mg/g tissue, ± S.E, n = 4 independent biological replicates) at 2 DPE. Panels (C, D) the histogram bars indicate mean numbers of YLS at 2 DPE and 3 DPE. Panel (E) Mean soluble ovarian protein content (mg/g) at 2 DPE. Panel (F) Mean soluble fat body protein content (mg/g) at 2 DPE. Histogram bars annotated with the same letter are not significantly different (t-test, $p < 0.05$).
to 3.01 μg/mg), compared to controls and by 25% (from 4.03 μg/mg to 3.01 μg/mg), compared to dsGFP-treated controls, again at 2 DPE (Fig. 2B).

Mating with males exposed to similar NlSPATA5-suppressing treatments led to significantly decreased YPS abundance of fat bodies in adult females at 2 and 3 DPE (Fig. 2C,D) \((F = 342.0, df = 2, 14, P = 0.0001\) for 2 DPE; \(F = 143.8, df = 2, 4, P = 0.0001\) for 3 DPE), down by 54% (from \(2.66 \times 10^{6} / \text{mL}\) to \(1.22 \times 10^{6} / \text{mL}\)) compared to untreated controls and by approximately 55% (from \(2.73 \times 10^{6} / \text{mL}\) to \(1.22 \times 10^{6} / \text{mL}\)) relative to dsGFP-treated controls at 2 DPE. By 3 DPE, YPLs were down by 39% from \(3.50 \times 10^{6} / \text{mL}\) to \(2.13 \times 10^{6} / \text{mL}\) compared to mating with untreated controls and by approximately 40% (from \(3.56 \times 10^{6} / \text{mL}\) to \(2.13 \times 10^{6} / \text{mL}\)) compared to mating with dsGFP-treated controls.

Dietary dsNlSPATA5 treatments in males led to significantly decreased soluble ovarian protein content and soluble fat bodies protein content in their mating partners at 2 DPE (Fig. 2E,F) \((F = 6.82, df = 2, 11, P = 0.016\) for ovary; \(F = 60.5, df = 2, 11, P = 0.0001\) for fat body). Mating with males treated with dietary dsNlSPATA5 led to reduced soluble ovarian protein content, down significantly by 27% (from 3.98 μg/mg to 2.87 μg/mg) compared to untreated controls and by approximately 32% (from 4.24 μg/mg to 2.87 μg/mg) relative to dsGFP-treated male controls (Fig. 2E) at 2 DPE. We recorded similar reductions in soluble fat body protein content, down by about 48% (from 4.32 μg/mg to 2.17 μg/mg) compared to untreated controls and by approximately 53% (from 4.67 μg/mg to 2.17 μg/mg) compared to mating with dsGFP-treated controls (Fig. 2F) at 2 DPE.

Dietary dsNlSPATA5 led to malformed reproductive systems. Compared to untreated males (Fig. 3A) and dsGFP-treated males (Fig. 3B), dietary dsNlSPATA5 led to significant malformation of vas deferens and seminal vesicle in males at 2 DPE (Fig. 3C), but no externally visible effect on testes and accessory glands was observed (Fig. 3C).

The external morphology of ovaries prepared from females after mating with experimental males, was also influenced by dietary dsRNA construct. The ovarioles within ovaries of females that mated with untreated males (Fig. 3D) or with dsGFP-treated males, (Fig. 3E), contained one or two fully developed banana-shaped oocytes at 2 DPE. However, mating with males exposed to dietary dsNlSPATA5 treatments resulted in undeveloped ovaries and severely inhibited oocyte growth in the ovaries (Fig. 3F). No fully developed oocytes were observed at 2 DPE in the dsNlSPATA5 group (Fig. 3F).

dsNlSPATA5 did not influence adult body weight or longevity. Dietary dsNlSPATA5 treatments did not influence adult longevity (Fig. 4A,B) \((F = 0.29, df = 2, 53, P = 0.07\) for males; \(F = 0.21, df = 2, 53, P = 0.81\) for females) and body weight (Fig. 4C,D) \((F = 3.0, df = 2, 14, P = 0.09\) for males; \(F = 0.75, df = 2, 14, P = 0.49\) for females).

Influence of dietary dsNlSPATA5 on reproduction parameters. The pre-oviposition period is the time, in days, from adult emergence to the onset of egg-laying. Mating with males exposed to dietary dsNlSPATA5
treatments prolonged the pre-oviposition period of females \( (F = 6.7, \text{df} = 2, 53, P = 0.003) \), increasing by 1.4 day (from about 4.4 to 5.8 days), compared to untreated controls (delayed by circa 31%) and dsGFP control (delayed by about 26%) (Fig. 5A). Dietary dsNISPATA5 treatments did not influence the oviposition period (Fig. 5B) compared to untreated and dsGFP controls \( (F = 1.3, \text{df} = 2, 53, P = 0.29) \).

The dsNISPATA5 treatments significantly decreased the number of laid eggs adult females \( (F = 9.4, \text{df} = 2, 53, P = 0.0003) \), down by 32% (from 387.4 eggs/female to 260.1 eggs/female) compared to untreated females and by approximately 29% compared to dsGFP females (from 368.2 eggs/female to 260.1 eggs/female) (Fig. 5C).

**Dietary dsNISPATA5 led to reduced Nlvg mRNA expression.** We examined the expression level of Nlvg mRNA in adults mating with dsNISPATA5-treated and control males. Mating with males exposed to dietary dsNISPATA5 treatments led to significantly down-regulated Nlvg expression at 2 DPE \( (F = 13.8, \text{df} = 2, 8, P = 0.006) \), down by 34% compared to dsGFP females and by approximately 30% compared to females that mating with dsGFP-treated males at 2 DPE (Fig. 6).
Figure 5. Influence of dietary dsNISPATA5 on reproduction parameters. Panel (A) The dietary dsNISPATA5 treatments led to increased pre-oviposition periods. Panel (B) The dsNISPATA5 treatments did not influence the oviposition period. Panel (C) The dsNISPATA5 treatments led to reduced fecundity. Histogram bars represent mean number of days (Panel A,B) or numbers of eggs (Panel C) ±SEM. Histogram bars annotated with the same letter are not significantly different at $p < 0.05$.

Figure 6. Mating with males exposed to dietary dsNlst6 led to decreased Nlvg mRNA expression at 2 DPE. Values were normalized relative to the reference gene, β-actin. Histogram bars represent the mean values ± SE (n = three replicates). Histogram bars annotated with the same letter are not significantly different (t-test, $p < 0.05$).
Discussion
The data reported in this paper strongly support our hypothesis that suppressing NISPATA5 expression in males will influence the post-mating behavior and physiology of female partners, which would reduce BPH fitness in agroecosystems. Our data show that 1/NISPATA5 is expressed at substantial levels for at least the first seven days following male adult emergence; 2/dietary dsNISPATA5 treatments led to reduced NISPATA5 expression, reproductive system development and Acps protein contents in males; 3/similar treatments with experimental males led to reduced numbers of YLS, ovarian development and soluble ovarian and soluble fat body protein contents in their untreated female partners; 4/dietary dsNISPATA5 treatments in males altered female reproductive biology, including increased length of preoviposition periods and reduced Nlvg expression and egg laying. These treatments did not influence adult longevity, body weights or the oviposition periods. Taken together, these data indicate that suppressing expression of NISPATA5 in males strongly altered some, but not all, aspects of female reproductive biology. The significance of this finding lies in a direct demonstration of the influence of a single male-derived protein on female mating partners.

SPATA5 is a member of the ATPase associated with diverse activities protein super-family (AAA-protein super-family). There are five major groups of AAA-proteins that evolved in every form of life, including viruses. They act in such varied functions as organelle membranes, DNA replication and repair, protein degradation, and cilia and flagellar movement. SPATA5, also known as spermatogenesis associated factor (SPAF), and ATPase family protein 2 homolog, was first discovered in mouse testes, where it is expressed in the early stages of spermatogenesis. It may also act in functional mitochondrial transformations during spermatogenesis. The biological significance of SPATA5 goes far beyond spermatogenesis, however, because mutations in human SPATA5 lead to susceptibility to the hair loss disorder, alopecia areata, and to microcephaly, intellectual disability and other serious disorders. As well as in transformation of cancer cells, it is also expressed in insects and Drosophila, and it is expressed in several insect tissues, including reproductive tissues. Our findings indicate that sexually transferred NISPATA5 is necessary to achieve full reproductive potential in the BPH mating system.

Work on individual genes and on global protein expression in insecticide- and jingGANGmycin-treated BPH demonstrates the enhancing influence of agricultural chemicals on BPH reproduction and population changes. The influence of these chemicals operates through multiple systems, including carbohydrate transport, protein biosynthesis, developmental hormones and lipid biosynthesis. Treating males with either of the insecticides, the organophosphate tpx or the pyrethroid, deltamethrin, led to increased protein contents in treated males and in untreated females after mating with treated males. These treatments also led to increased fecundity in untreated females after mating with treated males. This work establishes the idea that male BPHs transfer fecundity-improving proteins to their sexual partners.

NISPATA5 is expressed throughout the first seven days of male adulthood, indicating the protein is available for sexual transfer to females during each mating. Dietary dsNISPATA5 led to reduced expression of the cognate gene and inhibition of vas deferens and seminal vesicle development, which in turn led to reduced Acps proteins in males. Suppressing NISPATA5 expression in males strongly influenced females, with reduced ovarian and fat body protein contents and inhibition of oocyte growth in the ovarioles. We emphasize these effects do not follow from toxic mechanisms because dsNISPATA5 treatments did not influence body weight or longevity of males or their female partners. Proteins, of course, are critical to achieve full reproductive potentials. We registered the reduced ovarian and fat body protein contents in terms of fecundity, showing substantial reductions in numbers of eggs deposited by females whose mating partners had been treated with dietary dsNISPATA5. Understanding that cells produce thousands of proteins raises questions about which proteins may be lacking in BPH partners that mated with dsNISPATA5-treated males. For a first look at how the dsNISPATA5 treatments in males influence protein contents in females, we considered the yolk protein, vitellin (Vt) because it is a specific protein within ovarian follicles and acts exclusively in egg development. Vitellogenin (Vg) is generally produced in fat body and becomes Vt in the process of receptor-mediated uptake from hemolymph circulation into eggs. The relative expression of Nlvg encoding Vg was reduced in females after mating with dsNISPATA5-treated males. We infer that NISPATA5 encodes a male-specific AAA-family protein that is necessary in females for biosynthesis of Vg and possibly other proteins used to achieve the full reproductive potential of BPH.

Our findings show that dietary dsNISPATA5 treatments reduced YLS abundance in females. A substantial relationship between YLS and amino acid requirements in BPH has been documented. Meeting essential amino acid requirements was associated with the abundance of YLS. Artificial reduction of the symbiont abundance led to delayed growth and decreased survival, adult emergence, body weight, and fecundity. Symbiotic bacteria in pea aphids also significantly influenced amino acid metabolism. Generally, the YLS provide essential amino acids and possibly proteins required for host embryo formation and post-embryonic development. The symbionts are essential to meet nutritional amino acid needs for production of a full complement of proteins. We infer dietary dsNISPATA5 treatment in males leads to reduced transfer of accessory gland proteins (including nutrition substances) to females via mating.

We hope to appreciate the biological significance of the sexual transfer of NISPATA5 by placing this finding in the context of insect mating systems, many of which include mechanisms that enhance female fecundity and ensure paternity, ranging from nuptial gifts to mate guarding to substances transferred to females within seminal fluids. For a single example, the Australian field cricket, *Teleogryllus commodus*, mating system involves male calling, which attracts receptive females to the males’ mating arenas. Mating occurs via a spermatophore, which delivers seminal fluids into the spermatheca. The seminal fluids include sperm, a specific protein, prostat gland (PG) synthe, and the lipid substrate for PG synthesis, arachidonic acid (AA). The AA is converted into PG within the spermatheca, which is transported in hemolymph to the terminal abdominal ganglion, where it releases a sequential behavioral program that ends in deposition of hundreds of fertilized eggs over the next several hours. Males ensure paternity by guarding their partners until the egg-laying program is completed. While NISPATA5 does not appear to influence female sexual behaviors, it exerts profound molecular and biochemical effects on
production of Vg and likely other proteins and these effects can be directly registered at the levels of organismal reproduction and BPH population dynamics.

Materials and Methods

Rice variety and culture. Rice (Oryza sativa L.) variety Ninjing 4 (japonica rice, commonly grown in Jiangsu province) was used in all experiments. Seeds were sown outdoors in cement tanks (height 60 cm, width 100 cm, and length 200 cm) containing standard rice-growing soil. When seedlings reached the six-leaf stage, they were transplanted into 16 cm diameter plastic pots containing four hills per pot, three plants per hill and used for experiments at the tillering stage.

Insect culture. BPHs were obtained from a laboratory population maintained in a greenhouse under our standard conditions (26 ± 2 °C, with 70–80% humidity and a 16L:8D photoperiod) at Yangzhou University. The insect colony was originally obtained from the China National Rice Research Institute (Hangzhou, China). Before the experiments started, the colony was allowed to reproduce for two generations in cement tanks (60 × 100 × 200 cm) under natural condition in Yangzhou.

dsRNA. We designed gene-specific dsNISPATA5 primers and amplified a 407-bp (422–828bp) NISPATA5 cDNA fragment using forward and reverse primers containing the T7 primer sequence at the 5’ ends (Table 1). The amplification program was 35 cycles of 95 °C for 40 s, 57 °C for 40 s and 72 °C for 1 min, with a final extension step of 72 °C for 10 min. The sequence was verified by sequencing (Invitrogen, Shanghai, China). We used the GFP gene (ACY56286; provided by Zhang Chuan-xi, Institute of Insect Sciences, Zhejiang University) as control dsRNA.

Table 1. PCR primers used in this study.

| Primers     | Primer sequence                              | Product size |
|-------------|----------------------------------------------|--------------|
| For real-time PCR | Q-NISPATA5-F CAGGCTCAAGGAGATACGG (Tm = 59.7 °C) | 127 bp       |
|             | Q-NISPATA5-R CCTTCAGCTTACGGATT (Tm = 52.7 °C) |              |
|             | Q-Nifr-F GTGGCTCTATACGGGAAGG (Tm = 58.0 °C)   | 200 bp       |
|             | Q-Nifr-R GCATTCAGCTTACGGATT (Tm = 60.2 °C)   |              |
|             | Actin-F TGCGTGACAATCAAGGGAAGG (Tm = 60.0 °C)  | 186 bp       |
|             | Actin-R CCATACCAAGAAGGAAAGGT (Tm = 60.0 °C)   |              |

For dsRNA synthesis

| NISPATA5-F   | TAATACGACTCACTATAGGG (T7 promoter) CCGCTGAAATGAAAGG (Tm = 51.6 °C) | 407 bp       |
| NISPATA5-R   | TAATACGACTCACTATAGGG (T7 promoter) GTTCGCAAGCAGATT (Tm = 51.6 °C)  |              |

For dsRNA synthesis

| NlGFP-F      | TAATACGACTCACTATAGGG (T7 promoter) AAGGCGAGGAGCTCAGG-3 (Tm = 60 °C) | 688 bp       |
| NlGFP-R      | TAATACGACTCACTATAGGG (T7 promoter) CAGCAGACCATAGTGCACGC-3 (Tm = 56 °C) |              |

Influence of dietary dsRNA on biological performance parameters. We determined the effects of dsNISPATA5 treatments on selected biological performance parameters. In preliminary experiments, we exposed

SCIENTIFIC REPORTS | 6:28111 | DOI: 10.1038/srep28111
second instar nymphs to the dsRNA construct, which led to over 95% mortality. Thereafter, we transferred 3rd instar nymphs to capsules containing dsRNA-laced diet. At their fifth (final) instar (8 days), they were collected and nymphs were individually transferred into a glass jar (12 cm high × 10 cm) and reared on tillering rice plants under 26 ± 2°C and 16L:8D. Eighty adult females and 80 adult males were collected separately at days 2 after emergence, and fresh body weight, soluble ovary protein content and soluble fat body protein content, soluble MAGs protein content and NISPATA5 expression level were determined. We paired individual newly-emerged females with a male. Each pair (♂ × ♀) was maintained in a glass jar (diameter 10 cm, height 12 cm) with rice seedlings under our standard conditions for oviposition. Eighteen copulating pairs were maintained to record duration of the pre-oviposition period, oviposition period, adult longevity, and fecundity for each pair. Rice stems were replaced daily during the pre-oviposition period, at two day intervals during the oviposition period and three day intervals during the female longevity period until the females died. The numbers of eggs laid on each rice stem was recorded under a light microscope. Eggs were scraped from the leaf sheaths and blades using a pin. Fecundity of 18 mated pairs was recorded as the average number of eggs laid.

**Protein Extraction and determinations.** Protein was extracted from fat bodies and ovaries using a method similar to Gong et al. Individual adult females in all 15 females were dissected under a zoom stereomicroscope (model XTL20, Beijing Tech Instrument Co., Ltd., Beijing, China) in a cooled petri dish. Ovaries and fat bodies were removed and placed in separate, pre-weighed, ice-cold centrifuge tubes and then re-weighed using a Mettler-Toledo electronic balance (EC100 model; 1/10,000 g sensitivity). A proportional amount of NaCl solution (0.4 M NaCl: 1 M PMSF, v:v at a ratio of 20 mL NaCl solution to 1 g ovary or fat body) was added to the tube, homogenized on ice, and centrifuged at 16,000 × g at 4°C for 20 min. The supernatant was collected after filtering the upper fat layer with glass fibers, placed at 4°C overnight after adding ddH2O (1 supernatant: 10 ddH2O, v:v), and centrifuged again at 4,000 × g at 4°C for 20 min. The protein sediment was dissolved with 1.5 ml pre-chilled 0.4 M NaCl solution after removing the supernatant. Protein from MAGs was extracted using the methods of Ge et al. Individual adult males in all 30 males were dissected under a zoom-stereomicroscope (model XTL20, Beijing Tech Instrument Co., Ltd., Beijing, China) in a cooled petri dish. MAGs were removed and placed in separate, pre-weighed, ice-cold Eppendorf tubes. To each tube, 600μL of mixed solution (methanol/distilled water/ acetic acid/methyl thioethanol; 80:18:2:0.1: v:v:v:v) was added. The contents were then homogenized on ice and centrifuged at 12,000 × g at 4°C for 10 min. The supernatant was collected after removing the upper fat layer. Four hundred μL of mixed solution was added to the sediment in the tube, which was then centrifuged again and the supernatant collected.

We followed Bradford to measure protein content using Coomassie Brilliant Blue R250 (Shanghai Chemical Agent Co., Ltd., Shanghai, China). A standard curve was established based on a BSA standard protein (Shanghai Biochemistry Research Institute, Shanghai, China). The absorbance at 595 nm was determined in a UV755 B spectrometer (Shanghai Precision Instrument Co., Ltd., Shanghai, China). The protein content in the sample solution was calculated according to the standard curve. Protein determinations were repeated four times, with four independent biological samples.

**Observation of the number of yeast-like symbionts (YLS) in fat bodies.** The procedure described in Noda was followed to measure the number of yeast-like symbionts (YLS) of fat bodies with blood cell counter (0.01 mm, 1/400 mm²) (25 * 16 model, Shanghai Qiujing Biochemical Reagent Co., Shanghai, China). We transferred 3rd instar nymphs to capsules containing dsRNA-laced diet; at their fifth (final) instar (8 days), nymphs were individually transferred into a glass jar (12 cm high × 10 cm) and reared on tillering rice plants under 26 ± 2°C and 16L:8D. We paired individual newly-emerged females with a male. Each pair (♂ × ♀) was maintained in a glass jar (diameter 10 cm, height 12 cm) with rice seedlings under our standard conditions for observation of the number of yeast-like symbionts (YLS) in fat bodies. Sixty uniform adult females were collected separately at 2 or 3 days after mating. Fat body was dissected from six adult females in treated or untreated control groups and homogenized gently in 20μL of 0.4 M NaCl solution after removing the supernatant. Protein from MAGs was extracted using the methods of Gong et al. Eighty adult females were collected in a glass jar (diameter 10 cm, height 12 cm) with rice seedlings under our standard conditions for observation of the number of yeast-like symbionts (YLS) in fat bodies. Sixty uniform adult females were collected in a glass jar (diameter 10 cm, height 12 cm) with rice seedlings under our standard conditions for observation of the number of yeast-like symbionts (YLS) in fat bodies. Sixty uniform adult females were collected in a glass jar (diameter 10 cm, height 12 cm) with rice seedlings under our standard conditions for observation of the number of yeast-like symbionts (YLS) in fat bodies. Sixty uniform adult females were collected in a glass jar (diameter 10 cm, height 12 cm) with rice seedlings under our standard conditions for observation of the number of yeast-like symbionts (YLS) in fat bodies.

**Body weights.** Five females or five males were used as a replicate at day 2. The insects were placed in pre-weighed centrifuge tubes and then weighed using a Mettler-Toledo electronic balance (EC100 model; 1/10,000 g sensitivity). Each treatment and control experiment was replicated five times with five independent sets of insects.

**qPCR analysis.** We isolated total RNA from the five newly-emerged females, using a SV Total Isolation System Kit (model Z3100, Promega Corporation, Madison, WI, USA). First-strand cDNA was synthesized in a 10μL reaction volume containing 0.5μg of RNA, 0.5μL of PrimeScript RT enzyme mix I, 0.5μL of Oligo dT primer (50μM), 2μL of random hexamers (100μM), 2μL 5× PrimeScript Buffer (for real-time-PCR) and RNase-free dH2O up to a final volume of 10μL, following the PrimeScript RT Kit instructions (TaKaRa Biotechnology, Dalian, China). The cDNA was reverse transcribed using the following program: 37°C for 15 min, 85°C for 5 s and 4°C for 5 min.

We similarly isolated total RNA from the dsRNA-treated and control adults. Portions (2μL) of the synthesized first-strand cDNA were amplified by qPCR in 20μL reaction mixtures using a CFX96 real-time PCR system (Bio–Rad Co. Ltd., California, USA). We used two qPCR programs. For NISPATA5, 94°C for 2 min, followed by 40 cycles of 94°C for 5 s, 56°C for 30 s and 72°C for 30 s. For NlVitellogen (Nlvg), 94°C for 2 min, followed by 40 cycles of 94°C for 5 s, 60°C for 30 s and 72°C for 30 s.
cycles of 94 °C for 5 s, 59.7 °C for 30 s and 72 °C for 30 s. NISPATA5 (NLU004890) and Nlv (AB353856) mRNA levels were separately quantified in relation to the stable expression of constitutive actin-1 (EU179846). Primers used for qPCR analysis are listed in Table 1. After amplification, a melting curve analysis was performed in triplicate and the results were averaged. The values were calculated using three independent biological samples and the 2^{-△△CT} method was used for the analysis of relative NISPATA5 expression level.

Statistical analysis. Before performing an analysis of variance (ANOVA), data were evaluated for normality and homogeneity of variance using a Bartlett test. Based on these evaluations, no transformations were needed. The results presented in figures are expressed as the means ± S.E. Two-way (days post-emergence and dsRNA treatment) ANOVAs were performed to analyze data in Fig. 1B. One-way ANOVAs were performed to analyze all other data except for Fig. 1B. Multiple comparisons of the means were conducted using Fisher’s Protected least significant difference (LSD) test. All analyses were conducted using the data processing system (DPS) of Tang and Feng.
