(Dated: November 27, 2008)

We present a surface trap which allows for studying the coherent interaction of ultracold atoms with evanescent waves. The trap combines a magnetic Joffe trap with a repulsive evanescent dipole potential. The position of the magnetic trap can be controlled with high precision which makes it possible to move ultracold atoms to the surface of a glass prism in a controlled way. The optical potential of the evanescent wave compensates for the strong attractive van der Waals forces and generates a potential barrier at only a few hundred nanometers from the surface. The trap is tested with \(^{87}\)Rb Bose-Einstein condensates (BEC), which are stably positioned at distances from the surfaces below one micrometer.

PACS numbers: 42.50.-p, 32.80.Qk, 03.75.-b, 34.35.+a

The interaction of ultracold atoms with surfaces has attracted much attention in the past for various technological and fundamental reasons. By the use of repulsive evanescent waves (EW) at a prism surface atom mirrors were constructed, from which both atomic beams and cold atomic clouds were reflected \cite{1,2}. EWs were also used for generating steep surface traps in which two-dimensional Bose-Einstein condensates can be prepared \cite{3}. Atom-surface interactions are also interesting for investigating fundamental aspects of quantum electrodynamics. Close to surfaces the electromagnetic vacuum fluctuations lead to the emergence of surface potentials like van der Waals or Casimir-Polder potentials. These potentials have been measured with hot atomic beams \cite{4}, in vapor nanocells \cite{5} in atomic mirrors \cite{6}, by quantum reflection \cite{7,8,9,10} and in magnetic traps \cite{11}.

Inspired by the first atom mirror experiments, proposals have been developed for non-destructive detection of atoms by evanescent waves with the perspective of QND measurements of atomic number fluctuations \cite{12,13}. The idea was that atoms interacting with an EW act as a refractive index medium and thereby shift the phase of the totally reflected light field. A measurement of this phase shift should therefore reveal the atom number. By choosing a large detuning of the light frequency from atomic resonances, the atomic cloud remains undisturbed by this measurement. This proposal is complementary to experiments with resonant light fields which allow to measure the atom number destructively \cite{14}. In the situation considered in \cite{12} atoms are released from a magneto-optic trap (MOT) and bounce off an atom mirror. A quantitative analysis revealed a very small phase shift which will be barely detectable. The main problems are the facts that (i) the density of atoms from the MOT is too low and (ii) the interaction time during the reflection is very short which results in a high shot noise. Other problems with reflection experiments are random scattering due to surface roughness \cite{15,16,17}. We are able to circumvent these problems by using BECs which have four orders of magnitude larger densities and by keeping the atoms in a trap, which allows for adjusting the interaction time. Calculation with our parameters following the methods in \cite{12} result in detectable phase shifts on the order of \(\Delta \phi \sim 10^{-4}\) rad and signal to shot-noise ratios on the order of a few thousand.

The surface trap presented here uniquely combines the advantages of evanescent waves and magnetic fields. Magnetic traps have the advantage that they can be easily shifted by offset fields such that the atoms can be brought to the surface in a controlled way. However, magnetic traps are less steep than dipole traps. Therefore the problem occurs that the magnetic trapping potential is opened by the attractive Casimir-Polder potential close to surfaces which leads to the loss of atoms \cite{18}. This can be avoided by an additional dipole potential that is generated by a blue detuned evanescent

\[ \begin{align*}
\text{FIG. 1: (a) Schematic view of the prism. The magnetic trap is situated below the prism surface at a distance } z_0 \text{ and can be shifted towards the surface, where the Casimir-Polder force and the repulsive dipole potential become dominant. This is illustrated in (b), where the Casimir-Polder potential } U_{\text{CP}} \text{ and the evanescent wave potential } U_{\text{EW}} \text{ add up to form a potential barrier at few hundred nanometers from the prism surface.} \end{align*} \]
wave (Fig. 1 a). The repulsive dipole potential is able to partially compensate for the Casimir-Polder potential thereby producing a potential barrier at only a few hundred nanometers from the surface (Fig. 1 b). This potential barrier prevents the atoms from being lost when the magnetic trap is shifted to the surface.

In the following, simulations of our combined surface trap are shown. The trapping potential is determined by the Casimir-Polder potential $U_{\text{CP}}$, the evanescent wave potential $U_{\text{EW}}$, the magnetic trapping potential $U_{\text{magn}}$ and the gravitational potential $U_g$

$$U_{\text{tot}} = U_{\text{CP}} + U_{\text{EW}} + U_{\text{magn}} + U_g.$$  

(1)

For the simulation of the surface potential, we use the formula for the retarded regime

$$U_{\text{CP}}(z) = \frac{C_4}{\omega^2},$$  

(2)

with $z$ the distance from the surface and

$$C_4 = \frac{1}{4\pi\epsilon_0} \cdot \frac{3\hbar c \alpha(0)}{8\pi} \cdot \frac{\epsilon(0) - 1}{\epsilon(0) + 1} \cdot \Phi(\epsilon(0)),$$  

(3)

where $\epsilon_0$ is the dielectric permittivity of vacuum, $c$ the speed of light, $\alpha(0) = 5.26 \cdot 10^{-39}$ Fm$^2$ the static polarizability of Rb, $\epsilon(0) = 2.25$ the static dielectric constant of the glass substrate corresponding to a refractive index of $n = 1.5$ and $\Phi(2.25) = 0.29$ is given by a formula in [19]. From these values we get a $C_4$ coefficient of $C_4 = 1.78 \cdot 10^{-55}$Jm$^4$. At the distances relevant for our simulations the formula of the retarded regime (2) is a sufficient approximation, although more precise interpo-

lation formulas exist [9]. The evanescent wave potential exponentially decays with distance from the surface $z$ and has a gaussian shape in the transverse direction $x, y$ with beamwaists $w_{x,y}$.

$$U_{\text{EW}}(x, y, z) = U_0 \cdot \exp \left\{-\frac{z}{\lambda_p} - \frac{2x^2}{w_x^2} - \frac{2y^2}{w_y^2}\right\},$$  

(4)

where the penetration depth is given by $\lambda_p = \left(k \cdot \sqrt{n^2 \sin^2(\theta)^2 - 1}\right)^{-1}$, with $k = 2\pi/\lambda$ the wavevector of the light with wavelength $\lambda = 765$ nm and $\theta$ the incidence angle (see figure 1). The maximum value of the potential at the surface is given by the dipole potential

$$U_0 = \frac{\pi e^2 \Gamma}{2\omega^3} \cdot \frac{I_{\text{ev}}}{\Delta}$$  

(5)

with $\Gamma = 2\pi \times 6$ MHz the natural linewidth of the Rb 5P state, $\omega$ the frequency of light, $I_{\text{ev}}$ the maximum light intensity in the evanescent wave and $\Delta$ the mean detuning of the laser frequency from the Rb $D_1$ and $D_2$ line. The magnetic trap is harmonic

$$U_{\text{magn}}(x, y, z) = \frac{1}{2} m \left(\omega_x^2 x^2 + \omega_y^2 y^2 + \omega_z^2 (z - z_0)^2\right)$$  

(6)

with trap frequencies of $\omega_x \sim 2\pi \times 25$ Hz, $\omega_y = \omega_z \sim 2\pi \times 200$ Hz and $m$ the atomic mass. The magnetic field minimum is located at a distance from the surface $z_0$ which is adjustable in our experiment. In good approximation the transverse coordinates of the magnetic field minimum coincide with the position of maximum evanescent light intensity. Finally the gravitational potential is given by

$$U_g(z) = -mgz$$  

(7)

where the negative sign accounts for the fact that the prism is mounted upside down in the chamber.

![Figure 2](image-url)

**FIG. 2:** (a) Simulated potential and atom density for different positions of the magnetic minimum $z_0$: (i) $z_0 = 0 \mu m$, (ii) $z_0 = -5 \mu m$, (iii) $z_0 = -10 \mu m$ and (iv) $z_0 = -15 \mu m$. The curves are shifted relative to each other by 1 $\mu K$ for better visibility. In these simulations the laser power is $P = 500$ mW, the reflection angle is $\theta = 47.5^\circ$ corresponding to a penetration depth of $\lambda_p = 243$ nm and the beamwaists are $w_x = 170$ $\mu m$ and $w_y = 240$ $\mu m$. (b) Two-dimensional plot of the simulation result corresponding to curve (iv) in fig. (a). The atomic density is omitted here for clarity.

Figure 2 (a) shows simulations of realistic trapping potentials for different positions of the magnetic field minimum $z_0$. Negative values of $z_0$ correspond to magnetic field minima behind the prism surface. The actual position of the trap though is at positive $z$ values due to the combination with the other potentials. In addition, the atomic density in Thomas Fermi approximation is plotted for $N = 10^5$ atoms. By shifting the trap towards the surface the atomic cloud is compressed. Fig. 2 (a) shows a cut through the center of the trap along the $z$-axis. Fig. 2 (b) shows the simulated potential as a function of both $z$ and $x$ axis. A small reduction of the trap depth due to two saddle points is observed at about $x = \pm70 \mu m$, because of the transversal gaussian shape of the repulsive dipole potential.

The schematic setup of our experiment is sketched in Figure 3. At position A $^{87}$Rb atoms are collected in a magneto-optic trap. After loading into a purely magnetic trap the atoms are adiabatically transferred to a Joffe-Pritchard type of wire trap which is formed by a second pair of coils (BEC coils) and two wires which are
the evanescent wave potential barrier (regime (ii)). Only when the magnetic potential any more, but are held back by the evanescent wave potential barrier (regime (ii)). Only a small shift remains on the order of below 1 µm the atoms cannot follow the surface and then let adiabatically expanded for absorption imaging.

The Bose-condensed atoms are shifted in the magnetic trap to the surface. After the interaction they are withdrawn from the surface and then let adiabatically expanded for absorption imaging.

running vertically through the coils. There the atoms are further cooled by forced evaporation. Within this trap we can produce Bose-Einstein condensates with up to approximately 6·10^5 atoms. The special feature of this wire trap is the fact that it can be easily shifted vertically by applying an external offset field. By this we are able to move the atoms very close to the surface of a glass prism which is mounted at the upper magnetic coil. The prism being attached upside down enables us to analyze the atomic cloud after the interaction with the prism surface in time of flight (TOF) absorption imaging.

The position of the trap z_{min} as a function of the position of the magnetic field minimum z_0 is illustrated in Fig. 4(a). At distances of more than about one micrometer from the surface, the trap shifts with the magnetic field minimum. This is consistent with a linear fit of the simulated data points in regime (i) in figure 4(a) which shows a gradient of \( \frac{dz_{\text{min}}}{dz_0} = 1 \). The offset of 10 µm is due to gravitational sagging. At distances to the surface of below about 1 µm the atoms cannot follow the magnetic potential any more, but are held back by the evanescent wave potential barrier (regime (ii)). Only a small shift remains on the order of below \( \frac{dz_{\text{min}}}{dz_0} \sim 0.01 \). The magnetic field at the position of the atoms B_A therefore increases. We have measured this increase with radio-frequency (rf) spectroscopy. For each position of the magnetic field minimum the radio frequency is detuned at which the atoms are resonantly coupled to an untrapped Zeeman state and thus lost from the trap. The transition frequency is given by the magnetic field B via \( \hbar \omega_{\text{rf}} = g_F \Delta m_F \mu_B B \), with \( g_F \) the Landé factor, \( \Delta m_F \) the difference in the magnetic quantum number and \( \mu_B \) the Bohr magneton. By determining the minimum radio frequency at which atom losses occur we get the magnetic field at the bottom of the trap. The result is shown in Fig. 4(b). As we ramp the currents in the magnetic coils and thereby shift the magnetic trap towards the prism, we observe the transition from regime (i) where the magnetic offset field is constant to regime (ii) where it grows quadratically. A fit to the data reveals a magnetic trapping frequency of \( \omega_z = 2\pi \times 195 \text{ Hz} \), which is in good agreement with the value observed in trap oscillations. We have calibrated the relative shift of the magnetic field minimum to the currents in the magnetic coils by absorption imaging at larger distances from the surface. The absolute scale is fixed by the position where the magnetic offset field starts to rise quadratically. This position is taken from the simulation in Figure 4(a). As it turns out to be very robust against changes in the simulation parameters, we assume that the absolute position of the magnetic field minimum is calibrated to an error of approximately 1 µm.

With the help of the evanescent wave the atom losses occurring in magnetic traps close to surfaces are strongly reduced (Fig. 5). Here, a Bose-Einstein condensate is initially prepared in a magnetic trap at about \( z_{\text{min}} = 40 \mu m \) below the prism surface. Then the magnetic trap is shifted in \( \tau = 200 \text{ ms} \) towards the prism surface to a distance \( z_0 \) of the magnetic field minimum. In order to shift the atoms smoothly the
corresponding coil currents are ramped with a sinusoidal time dependance $I = I_0 + \Delta I \cdot \sin(\pi t/\tau)^2$. After the magnetic trap is immediately shifted back to its starting position within 100 ms, the atoms are released and counted. The experimental results are shown in Figure 5. Without the evanescent wave (curve a) the atoms are lost as soon as the Casimir-Polder potential opens up the magnetic trap. With the given magnetic trapping frequencies this occurs at a distance of the atoms from the surface of approximately 10 $\mu$m. The observed width of the decrease of atoms can be well explained by an energy spread given by the chemical potential of the BEC. However, with the evanescent dipole potential (curve b), the atoms can be shifted much closer to the surface. The position of the magnetic field minimum of several 10 $\mu$m behind the surface corresponds to a distance of the atoms from the surface of below 1 $\mu$m. At such small distances about half of the atoms are lost within the measuring time. This loss rate can be further reduced by increasing the laser intensity and thereby the potential barrier. We therefore attribute the atom loss to (i) the evaporation of atoms over the barrier and (ii) tunneling of atoms through the barrier.

We have described a surface trap which combines the flexibility of magnetic traps with the high gradients of evanescent dipole potentials. In such a trap atoms can be stably brought to the surface of transparent media with distances below 1 $\mu$m, which is the range of evanescent waves and surface potentials. This is the key for various experiments with cold atoms in which surface properties are investigated and exploited. Important examples are dispersive potentials due to van der Waals and Casimir forces [20], but also the fascinating idea of investigating bound surface-atom states by laser-induced quantum adsorption [21, 22], which is the analogue to photo-association of atoms. The crucial question herein is if atoms can be trapped in these highly excited bound states and if these traps can be tailored by a suitable structuring of the surface. In this context surface plasmon polaritons which can be used to locally enhance evanescent waves above surfaces are very promising [23].
